Abstract

Post-processing heat treatments (HT) are performed on Ti-6Al-4V components fabricated by Laser Powder Bed Fusion (L-PBF) to release the residual stresses and transform the nonequilibrium martensite into a dual-phase $\alpha + \beta$ microstructure. In the present study, postprocessing sub-transus HT are conducted at various annealing temperatures for 2 h, with slow cooling either in a larger volumetric horizontal industrial furnace or a smaller volumetric tubular laboratory furnace. These two different furnaces were chosen to significantly modify the atmosphere and generate an oxygen-affected layer on the surface. The results show that the higher the annealing temperature, the coarser the α laths and the higher the β phase fraction. An oxygen-enriched hard and brittle alpha-case layer was revealed only for HT performed in the industrial furnace. The provided data allowed modeling of the oxygen diffusion in Ti-6Al-4V made by L-PBF. It has been found that without the alpha-case, post-processing HT helps to balance the strength/ductility compromise of the alloy in relation to the microstructural evolution. On the other hand, when an alpha-case layer greater than 50 µm is present, the elongation to failure is impacted and decreases as the alpha-case depth increases. Meanwhile, the impact toughness is less affected and remains mainly microstructure-dependent. The loss in ductility was attributed to the presence of cracks that develop at the surface of the samples during tensile solicitation. The opening rate of the crack lips is proportional to the applied strain, and the cracks spread through the brittle alpha-case layer. It has been shown for the first time that the cracks are visible on the sample's surface for stress values lower than half of the material's yield stress. The post-processing HT at 800 °C for 2 h provided a strong and ductile Ti-6Al-4V, which showed a minor effect of the alpha-case on the tensile properties.

¹ 1 Introduction

Titanium alloys are widely used in aerospace industry due to their high strength-to-weight ra-2 tio and corrosion resistance. Among Ti alloys, ASTM grade 5 Ti-6Al-4V (Ti64) is the most used 3 titanium alloys for aerospace applications [1–3]. Ti64 is a dual-phase $\alpha + \beta$ alloy with excellent 4 mechanical properties and was developed in the 1950s for aircraft structures. It currently holds 5 almost half of the titanium products market share. The manufacturing process of Ti64 compo-6 nents typically involves casting, forging and rolling steps, followed by subsequent machining to 7 obtain the final shape [4, 5]. In recent years, the needs of the aeronautic industry to reduce parts 8 weight, material waste and assembled components have allowed metal additive manufacturing 9 (AM) techniques to be considered a serious alternative to the conventional processes mentioned 10 above [6, 7]. In particular, AM of the Ti64 alloy by Laser Powder Bed Fusion (L-PBF) has 11 gained significant attention for producing complex geometries and high performance compo-12 nents. L-PBF allows for the production of near-net-shape parts and the technique has become 13 mature enough to consider manufacturing structural components for specific applications that 14 require a strong material integrity [7-13]. The L-PBF process is described for example in [6] or 15 [7]. 16

Due to the high thermal gradients generated during the manufacturing of Ti64 through L-PBF. 17 as-built parts are exposed to high tensile residual stresses near the surface [14-17]. These residual 18 stresses can adversely affect the mechanical behavior of the material [18, 19]. Furthermore, 19 due to the high cooling rates involved during the process, as-built L-PBF Ti64 presents an α' 20 martensitic microstructure consisting of fine, hierarchical, and entangled needles [20, 21]. Upon 21 cooling, the α' phase germination is preceded by the formation of columnar β grains with a 22 morphological and crystallographic texture oriented parallel to the building direction [22-25]. 23 The martensitic structure that grows in the parent β grains is typically associated with high 24 mechanical strength but poor ductility [21, 26–30] and limited fatigue properties [31, 32]. To 25 meet the product requirements in terms of static [33] and dynamic mechanical behavior, post-26 processing operations can be performed on Ti64 components. In particular, post-processing 27 heat treatments (HT) are performed on as-built parts in the sub-transus range to relieve the 28 residual stresses and decompose the martensitic phase into an equilibrium $\alpha + \beta$ mixture, which 29 helps balance the strength / ductility compromise [28-31]. As it is well known that the presence 30 of residual stresses may lead to distortions of the as-built parts after cutting [13, 14, 34], the 31 stress-relieving HT carried out for industrial L-PBF production routines is directly performed on 32 components still attached to their base-plate to ensure the dimensional precision of the parts after 33 removal from the building platform. For components and base-plates of large dimensions, this 34 justifies the need for an atmosphere-controlled industrial furnace equipped with an appropriate 35 volume capable of performing suitable post-processing HT on several L-PBF productions. 36

³⁷ When exposed to elevated temperatures in an oxygen-containing environment, titanium and ³⁸ its alloys develop an oxide layer on the surface and an oxygen diffusion zone (ODZ) beneath it ³⁹ [35–37]. Due to the significant oxygen solubility in the α phase of titanium (up to 33 at%) [38],

the presence of higher oxygen contents in $\alpha + \beta$ alloys tends to stabilize the α phase at the expense 40 of the β phase, resulting in the ODZ commonly referred to as "alpha-case" (α -case). Oxygen 41 occupies the interstitial sites of the hexagonal close-packed (HCP) lattice of α titanium and limits 42 the mobility of dislocations [39]. As a result, the alpha-case acts as a hard and brittle layer [40, 43 41] that degrades the mechanical properties by initiating cracks at the surface under loading 44 [38, 42, 43]. The alpha-case created during high-temperature steps of conventional processes 45 such as casting or forging is typically removed from ingots or semi-products that are machined 46 into performance parts subjected to high static or dynamic loading. However, because the L-47 PBF products are fabricated near-net-shape, removal of an alpha-case layer generated during 48 post-processing HT involves an additional operation that can be expensive or even impossible 49 for complex geometry parts. 50

Designing suitable post-processing operations to enhance the mechanical properties of Ti64 51 alloy fabricated by L-PBF is currently of primary interest for industrial applications. The demon-52 strated economic viability of this manufacturing process primarily relies on a limited amount 53 and associated cost of required post-treatments [6, 7]. As mentioned above, numerous literature 54 papers focus on the effects of post-processing HT on microstructural and mechanical evolution of 55 Ti64 fabricated by L-PBF. Most of the studies utilized small volume laboratory furnaces, and the 56 vast majority of them tested tensile samples that were machined from rectangular or cylindrical 57 specimens. This means that the observed evolution of mechanical properties is induced by the 58 microstructural evolution only, without taking into account the substantial effects of the surface 59 and sub-surface states, including the possible presence of alpha-case. To date, very few studies 60 have addressed the presence of an alpha-case layer after post-processing HT of Ti64 fabricated 61 by L-PBF [44, 45]. In addition, to our knowledge, the effects of alpha-case layers of different 62 depths on the tensile properties of Ti64 fabricated by L-PBF have not been investigated yet. 63 Consequently, the present study aims to quantify the effects of both microstructural evolution 64 and alpha-case formation during post-L-PBF HT on the static properties of Ti64. To achieve 65 this, batches of samples were heat-treated at various annealing temperatures in an industrial 66 furnace or in a laboratory furnace, which involved different atmospheres and, thus, significant 67 changes in the alpha-case formation. The evolution in terms of microstructure, alpha-case, and 68 static properties is characterized for all batches and compared. 69

70 2 Materials and experimental methods

71 2.1 Material and process

A commercial batch of Ti-6Al-4V (Ti64) pre-alloyed spherical powder, manufactured by Tekna
Advanced Materials Inc., Canada, was used. The particles were plasma atomized, and their size
distribution ranges from 5 to 25 µm. The chemical composition of the powder batch is detailed
in Table 1. All L-PBF samples were built to near-net-shape using a FormUp 350 provided by

AddUp, France. The fabrication took place under an argon (Ar) protective atmosphere without 76 pre-heating of the base plates. The machine is equipped with dual YAG fiber lasers, with a 77 spot size of approximately 70 µm. Each of them was assigned to a specific area of the Ti64 base 78 plate corresponding to the front or back side of the building chamber. Both lasers applied a 79 meander scanning pattern with the scanning direction rotated by 90° between each layer. The 80 process parameters were optimized to obtain near-fully dense parts. Prior to testing, X-ray 81 computed tomography was performed on three vertical tensile specimens with a scan height of 82 23 mm for the whole specimen width and thickness. A voxel size of 6.5 μ m was used and the 83 equivalent diameter of the smallest pores after image analysis was 24 µm, which corresponds to 84 an equivalent volume of 26 voxels. With such parameters, the porosity for each sample is lower 85 than 0.005~% (hence density is higher than 99.995 %, and 99 % of the pores has an equivalent 86 diameter lower than 60 µm. From these results, it is expected that the internal defects play a 87 minor role in the static properties compared to the microstructural evolution [46]. 88

The orientations of the parts are defined in this work in accordance with the ISO/ASTM 52900 standard using the axis of the L-PBF machine, XY being the plane parallel to one deposited layer and Z being the building direction. For each of the six metallurgical conditions studied in this work, a fabrication step was performed to produce a batch including simple geometry samples (cubes, blocks), tensile bars, and Charpy impact specimens. In addition, a final fabrication containing vertical tensile and impact bars, similar to the ones from the six previous batches, was done.

Table 1: Chemical composition (wt%) of the batch of grade 5 Ti64 powder.

97 2.2 Post-processing heat treatments (HT)

The first batch of samples will be referred to as the as-built condition thereafter. Parts from 98 the five next batches will be referred to as the Industrial Furnace Heat Treatment (IF-HT) sam-99 ples. The tensile and impact bars from the supplementary fabrication will be referred to as the 100 Laboratory Furnace Heat Treatment (LF-HT) samples. For every HT performed in this study, 101 an annealing time of 2 h was set to relieve all the internal stresses generated during L-PBF 102 and to ensure a microstructural homogeneity in the entire volume of the thicker components. 103 Following the annealing, a slow cooling rate was employed to allow diffusion of the alloying 104 elements and to obtain a resulting microstructure close to the equilibrium conditions. 105

Post-processing IF-HT were performed directly after the fabrication step, with the samples still
attached to their base plate. The IF-HT were carried out by the Nadcap certified company
THERMI-GARONNE (France) in a BMI B84T horizontal gas quenching vacuum furnace. To
investigate the effects of annealing temperature on the microstructure and mechanical properties evolution, five temperature values ranging from 720 °C to 980 °C were selected within the

sub-transus domain of the alloy. The Samples' temperature was measured by placing a thermo-111 couple in contact with a Ti64 plate. The corresponding temperature curves for the five IF-HT 112 processes are displayed in Figure 1.a, along with the pressure curves. The IF-HT process involves 113 a preliminary heating above 100 °C for one hour under vacuum to eliminate potential moisture 114 that could penetrate the sample roughness during transportation. Subsequently, the heating 115 chamber is pumped up to a pressure of 1×10^{-4} mbar, and the heating step to the annealing 116 temperature is performed at an average of 10 $^{\circ}$ C min⁻¹. After completing the annealing time 117 of 2 h, the samples undergo a slow cooling process within the furnace, with the average cooling 118 rate ranging from 1.8 °C min⁻¹ for 720 °C IF-HT to 2.8 °C min⁻¹ for 980 °C IF-HT. Finally, 119 when the temperature reaches 400 °C, fast cooling is achieved by injecting Ar into the chamber. 120 Post-processing LF-HT were performed on untreated tensile bars and impact specimens that had 121 already been separated from the base plate. LF-HT were carried out in a Nabertherm RHTC 122 80-450/15 tubular vacuum furnace. The LF-HT cycles were designed with the same tempera-123 ture/time combinations. Temperature was measured with a type-S thermocouple placed nearby 124 the samples, and the corresponding temperature curves are available in Figure 1.b. No prelim-125 inary heating above 100 °C was made, but the samples were cleaned with an ultrasonic device 126 before LF-HT. After pumping the heating chamber up to a pressure of 1×10^{-2} mbar, a heating 127 step is performed at an average of 10 °C min⁻¹, followed by 2 h at the annealing temperature, 128 and then slow cooling in the furnace. The average cooling rate ranges from 4.1 $^{\circ}C \min^{-1}$ for 129 720 °C LF-HT to 4.7 °C min⁻¹ for 980 °C LF-HT. At 400 °C, the sample is removed from the 130 furnace and water-quenched. 131

Figure 1: Temperature-pressure curves of (a) Industrial Furnace Heat Treatments (IF-HT) and (b) Laboratory Furnace Heat Treatments (LF-HT).

Following the fabrication for the as-built condition or after IF-HT, samples were separated from the base plates by wire electro-discharge machining (EDM). This step resulted in minor distortions for as-built parts with smallest thicknesses, but it should be noted that no distortions were measured on the HT parts. In fact, it was shown in a previous study that an HT performed for 2 h at 720 °C allows relieving all the internal stresses generated during the fabrication [13].

¹³⁸ 2.3 Microstructural characterization

The microstructural characterization was conducted by Optical Microscopy (OM), X-ray 139 Diffraction (XRD), and Scanning Electron Microscopy (SEM). This slices of material, cut on 140 horizontal XY or vertical YZ cross-sections of 15 mm³ cubes at about 1 mm from the external 141 surface, were used. All the samples for microstructure examination were ground with 320 grit 142 size SiC paper followed by 9 µm diamond solution. They were then chemically and mechanically 143 polished with a mixture of 50 nm colloidal silica suspension, hydrogen peroxide, and ammonia. 144 Samples used for imaging the microstructure using Back-Scattered Electron (BSE) SEM mode 145 were vibratory polished with colloidal silica. Samples for XRD and Electron Back-Scattered 146 Diffraction (EBSD) were electropolished for 15 s with a solution consisting of perchloric acid, 147 ethanol and 2-butoxyethanol. OM pictures of IF-HT and LF-HT samples were taken with an 148 Olympus GX51 light microscope on the YZ plane of the grip section of tensile bars. The mi-149 crostructure was revealed by Kroll reagent etching. 150

Phase analysis by XRD was performed using a Malvern Panalytical X'Pert Pro MRD equiped with a Cu-K_{α} ($\lambda = 1.54$ Å) line focus X-ray source. The diffractometer operated at 45 kV with a tube current of 40 mA, and each scan covered 2 θ from 30° to 130° with a step size of 0.04°. It should be noted that due to the presence of crystallographic texture in the samples, XRD scans were conducted for qualitative comparison rather than quantitative evaluation.

- Surface phase fractions were determined from BSE images acquired using a ZEISS Supra 55 156 VP FEG-SEM. Image analysis was performed with ImageJ software to distinguish both phases 157 based on the contrast obtained. The calculated surface fraction represents the average of 20 158 images taken in the YZ plane for each condition. Additionally, the SEM was used to capture 159 secondary electrons (SE) images of the fracture surfaces of the tensile bars. EBSD was per-160 formed on the same SEM operating at 20 kV with an Oxford Instruments Symmetry camera. 161 EBSD maps with different sizes were recorded on the YZ plane for each condition, with a pixel 162 size ranging from 50 nm (as-built) to 150 nm (980 °C - 2 h). EBSD data were treated with 163 the MTEX toolbox [47] on MATLAB software, and α laths boundaries were detected with a 5° 164 misorientation threshold between grains. Grains smaller than 10 pixels were removed from the 165 grain maps, and the thicknesses of the resulting α laths population were determined using the 166 semi-minor axis after ellipse-fitting. Increasing map sizes (and corresponding pixel sizes) with 167 increasing HT temperatures allowed for obtaining the same order of magnitude of grain popula-168 tions for each condition, enabling a representative comparison of the evolution of the alpha lath 169 sizes. 170
- The alpha-case layer was revealed on samples polished in the XY plane of cubes using Weck reagent etching (ammonium bifluoride dissolved into ethanol and water) for approximately 30 s.
- ¹⁷³ Micrographs of the etched samples were captured with an Olympus GX51 light microscope. The
- alpha-case thickness was quantitatively measured using ImageJ software by analyzing 20 images
- taken along the entire perimeter of a cube.

176 2.4 Mechanical characterization

Tensile tests were performed for each condition on dog-bone-shaped specimens that were fab-177 ricated with dimensions of 35 mm (gauge length), 7 mm (width), and 3 mm (thickness). These 178 bars were built vertically. Therefore, the tensile load was applied parallel to the building di-179 rection Z. Three tensile samples were tested for the as-built, IF-HT and LF-HT conditions. 180 The tensile tests were conducted at room temperature using an Instron Model 1186 tensile sys-181 tem with a cross-head displacement rate fixed at $0.525 \text{ mm min}^{-1}$, resulting in a strain rate of 182 1.5×10^{-2} min⁻¹, in accordance with the NF EN ISO 6892-1 standard. A strain gauge exten-183 someter was employed for accurate strain measurement. The mechanical properties including 184 yield stress at 0.2 % plastic deformation (σ_y) , Ultimate Tensile Strength (σ_u) , and elongation 185 to failure (ε_f) were obtained as the average of three tests for each condition. 186

To assess the impact toughness of the material, Charpy impact tests were conducted on standard V-notch specimens fabricated vertically (impact direction orthogonal to Z) using an Amsler
Prüfsysteme impact testing machine. The absorbed energy (KV) represents the average value
of 5 specimens tested for the as-built, LF-HT and IF-HT conditions.

Vickers microhardness was measured on thin XY polished samples in the as-built, IF-HT and LF-HT conditions using a Buehler microhardness tester with a 1 kg load and an indentation time of 15 s. Indents were made at random locations on the sample's surface, and the reported value is the average of 20 measurements. Additionally, microhardness profiles were obtained from the sample's surface using an applied load of 100 g. The profiles were taken with a staggered arrangement to achieve a spatial resolution of 12.5 µm between each measurement.

To investigate the formation and growth kinetics of strain-induced cracks in the alpha-case layer, 197 in situ tensile tests were conducted inside the chamber of the ZEISS Supra 55 VP SEM using 198 the secondary electron imaging mode. As shown in Figure 2, vertical flat tensile samples were 199 cut using wire EDM from a block that had undergone IF-HT at 860 °C for 2 h. The tensile bars 200 were cut at the edge of the block to preserve the alpha-case layer formed in the sub-surface. 201 The samples were 35 mm long and the gauge dimensions were $8 \times 1 \times 1 \text{ mm}^3$. Tensile tests were 202 performed at a displacement rate of 0.1 mm min^{-1} using a Deben Microtest 2000E Series tensile 203 module placed inside the SEM chamber. The first test involved gradually increasing the applied 204 load, with pauses every 100 N (an average of 115 MPa) to closely observe the gauge surface and 205 detect any visible cracks. In the second test, an already formed crack was monitored to examine 206 its growth kinetics during the tensile test. 207

208

209 3 Results

210 3.1 Microstructural characterizations

Figure 3 shows cross-sections taken in the YZ plane for the as-built condition and after IF-211 HT at different annealing temperatures. The micrograph in the as-built condition reveals that 212 the microstructure consists of long columnar prior β grains whose morphological orientation is 213 parallel to the Z-axis. The formation of the β phase at high temperature is driven by the thermal **21**4 gradients along the building direction, and it grows in epitaxy across the deposited layers [48]. 215 Inside the prior β grains, very fine α' martensite needles are formed during cooling from the β 216 domain due to the process's high cooling rates [20, 49]. With an increase in HT temperature, 217 gradual changes occur: for HT at 720 °C and 800 °C, only slight microstructural modifications 218 are visible at this scale, whereas for HT higher than 860 °C, the presence of lamellar α phase is 219 highlighted. HT at 920 °C and 980 °C lead to a coarse microstructure with the detected presence 220 of globular α phase packets. It should also be noted that for all metallurgical states after HT, 221 the prior β grain structure is conserved, as all the annealing temperatures were chosen below 222 the transus temperature of the alloy. Microstructures obtained after LF-HT were also analyzed, 223 and the same observations are depicted. 224

Figure 4 presents the Vickers hardness under 1 kg load (HV_{1kg}) measured in the bulk of the material for the as-built condition and after post-processing HT. Both IF-HT and LF-HT show a similar decreasing trend, with hardness values decreasing from 422.2±3.1 in the as-built state to 339.4±4.6 after IF-HT at 980 °C. Slightly higher hardness is measured for LF-HT with increasing temperature. However, hardness values between identical IF-HT and LF-HT conditions are close, suggesting similar microstructures in terms of phase fractions and grain growth.

Figure 3: Optical microscope micrographs taken in the YZ plane of L-PBF fabricated Ti64 in its as-built condition and after various sub-transus IF-HT.

Figure 4: Evolution of hardness (HV_{1kg}) of L-PBF fabricated Ti64 in the as-built condition and after various sub-transus IF-HT and LF-HT.

In order to investigate and quantify the microstructural evolution from the as-built α' state (i.e. grain size and phase fraction), XRD spectra, BSE images, and EBSD orientation maps were obtained as shown in Figures 5, 6, and 7, respectively. XRD spectra and SEM pictures (BSE, EBSD) are presented for as-built and IF-HT conditions only, as they are assumed to be representative of the LF-HT microstructures as well. However, quantitative measurements (α laths thickness, β phase fraction) for the as-built, IF-HT, and LF-HT microstructures are provided in this study.

The XRD spectra displayed in Figure 5.a show that all the peaks in the as-built condition are 238 attributed to α' martensite. After HT, peaks corresponding to the body-centered cubic β phase 239 are detected at all five temperatures. As shown in Figure 5.b, the β (110) peak around 40° 240 exhibits an increase in intensity with increasing HT temperature, indicating a higher β phase 241 fraction. Additionally, the β (110) peak position is shifted to lower 2θ angles with increasing 242 temperatures. Despite these changes, the α phase remains the dominant fraction for all condi-243 tions, as the α peaks are significantly more intense than the β ones. Moreover, the full width at 244 half maximum (FWHM) of the α' peaks in the as-built condition is larger than that of the α'/α 245 peaks after HT. The presence of residual stresses is associated with a high dislocation density, 246 and therefore, a high stored energy that affects the shape of the diffraction peak [50]. Internal 247 stress relaxation during HT leads to thinner peaks [51]. 248

Figure 5: (a) X-ray diffraction (XRD) spectra of L-PBF fabricated Ti64 in the as-built condition and after various sub-transus IF-HT and (b) magnified view of the β (110) peak around 40°.

The α/β phases fraction evolution was estimated from SEM-BSE micrographs, similar to the 250 ones presented in Figure 6.a. The entangled microstructure and the needle-like structures of 251 the hexagonal phase are retained for each condition. However, the martensite decomposition 252 results in the redistribution of alloying elements. Specifically, the diffusion of the α -forming 253 element aluminium (Al) tends to enrich the α phase, while the diffusion of the β -forming el-254 ement vanadium (V) tends to enrich the β phase. The difference in atomic number between 255 alloying elements leads to varying contrast in BSE imaging between the α and β phases [28, 256 52]. According to the EBSD phase map in Figure 6.b, the β phase nodules (in red) germinate 257 between the α laths (in blue). Hence, the light areas on the BSE pictures are attributed to 258 the β phase, whereas the dark areas are attributed to the α phase. The average apparent β 259 phase fraction of every condition calculated from BSE pictures is presented in Figure 6.c. The 260

fraction ranges from 2.2±0.3 % for IF-HT at 720 °C to 7.0±0.5 % for IF-HT at 980 °C. The evolution follows the same trend for LF-HT conditions, with only slightly more β phase observed at higher annealing temperatures. It should be noted that this increase in the β phase fraction from 720 °C to 980 °C coincides with the intensity evolution of the β (110) peak in Figure 5.b.

Figure 6: (a) SEM-BSE micrographs of L-PBF fabricated Ti64 in the as-built condition and after various sub-transus IF-HT. (b) EBSD phase map of the specimen subjected to IF-HT at 920 °C for 2 hours. (c) Average apparent fractions of the β phase measured by image analysis from SEM-BSE images.

In Figure 6.a, it becomes evident that the size of both the α and β grains increases with higher annealing temperatures. As the thickness of α laths significantly influences the mechanical response of Ti64 alloy [21, 28, 53, 54], special attention was given to quantifying the evolution of the α laths morphology. To achieve this, α laths were identified from the EBSD orientation maps, as illustrated in Figure 7. During the cooling of the fusion bath in the L-PBF process, ²⁷¹ the $\beta \longrightarrow \alpha'$ transformation follows the Burgers Orientation Relationship (BOR) [55], resulting ²⁷² in an acicular microstructure composed of several (up to 12) α' variants within each parent β ²⁷³ grain [24, 56]. The presence of numerous ultra-fine α' needles growing in multiple directions ²⁷⁴ with various crystallographic orientations enables the numerical identification of α laths from ²⁷⁵ EBSD maps using a misorientation criterion. In contrast, adjacent α laths grouped in colonies ²⁷⁶ that share the same crystallographic orientation in lamellar Ti64 microstructures are more chal-²⁷⁷ lenging to distinguish through EBSD orientation maps [53, 57].

Figure 7: EBSD inverse pole Figure α orientation maps of L-PBF fabricated Ti64 in the as-built condition and after various sub-transus IF-HT. The maps were taken in the YZ plane of a cube, with the build direction Z serving as the reference.

After sub-transus HT, the α' transforms into $\alpha + \beta$ phases, while retaining the same morphological and crystallographic organization of the martensitic structure. Using grain detection on the six EBSD maps acquired in each condition, a grain population containing morphological information (apparent length, apparent thickness) was extracted. The population size converges

to an average of 5840 identified α' needles in the as-built condition, and an average of 2170 iden-283 tified α grains after IF-HT at 980 °C. Figures 8.a and 8.b display the apparent α laths thickness 284 distributions obtained from the data acquired through grain detection on EBSD maps. The av-285 erage α laths thickness for each condition is shown in Figure 8.c. The evolution with annealing 286 temperature follows an exponential trend, with the α laths becoming thicker as the temperature 287 approaches the beta transus of the alloy (around 1 000 °C). The values measured using this 288 EBSD method are similar for IF-HT and LF-HT conditions, with only slightly thicker α laths 289 after IF-HT. The values of α laths thickness and β phase fraction measured for the as-built 290 condition and after IF-HT and LF-HT conditions are summarized in Table 2, section 3.3. 291 292

Figure 8: Apparent thickness distribution of the α laths measured from Figure 7 an plotted with a bin width of (a) 0.1 µm, (b) 0.01 µm and (c) average apparent thickness measured for the as-built, IF-HT and LF-HT conditions.

293 3.2 Alpha-case characterisation

Figure 9.a displays representative micrographs of XY cross-sections taken at the edge of a cube 294 for each IF-HT condition. Figure 9.b exhibits representative micrographs of XY cross-sections 295 taken at the edge of a half tensile specimen before and after LF-HT. Chemical attack with Weck 296 reagent was performed on all the samples to reveal the alpha-case layer, which appears in white. 297 The contrast between the oxygen-enriched material (alpha-case) and the substrate allows for es-298 timating the depth of the alpha-case layer from these pictures. In the as-built state, no presence 299 of alpha-case was found. After IF-HT at 720 °C, a thin 11 ± 1 µm white layer is visible below 300 the surface of the sample. The alpha-case depth increases with the annealing temperature, and 301 the maximum measured thickness for IF-HT at 980 °C is 185 ± 8 µm. The average alpha-case 302 thickness values measured for all IF-HT conditions are reported in Table 2. However, as shown 303 in Figure 9.b for the condition at 980 °C for 2 h, no presence of alpha-case was revealed on the 304 samples after LF-HT. 305

It is widely acknowledged that the presence of oxygen trapped into the alpha-case layer con-306 tributes to an increase in the hardness of titanium alloys through solid solution strengthening 307 [40, 58]. Figure 10 shows microhardness profiles taken from the surface of Ti64 cubes for IF-308 HT at 860 °C, 920 °C, and 980 °C. For IF-HT at 720 °C and 800 °C, the lateral resolution 309 of 12.5 µm obtained with indents by applying a staggered arrangement was not sufficient to 310 obtain an exploitable profiles. In can be observed that the hardness decreases from the surface, 311 indicating a reduction in oxygen content [40, 41, 58]. The hardness then stabilizes at a constant 312 value close to the bulk hardness reported in Table 2. Using the measured microhardness values 313 and fitting them with an 8th-degree polynomial equation, the profile evolution was modeled. 314 The fitted data lines in Figure 10 show this modeling. Based on these fits, the alpha-case thick-315 nesses were estimated to be 62.5 µm, 112.5 µm, and 212.5 µm for IF-HT at 860 °C, 920 °C, and 316 980 °C, respectively. These thicknesses were determined at the points farthest from the surface 317 with a hardness value 5 % higher than the bulk hardness. These values are higher than the 318 estimated alpha-case thicknesses obtained from white-layer measurements on etched samples, 319 indicating that oxygen hardening is more sensitive to even small changes in oxygen content, 320 whereas only areas with the highest oxygen concentrations are revealed with chemical attack 321 using Weck reagent. This suggests that examination with optical microscopy alone could lead 322 to an underestimation of the alpha-case depth. 323

324

Figure 9: Optical microscope micrographs taken at the edge of cross-sections in the XY plane of (a) cubes before and after various IF-HT conditions, and (b) half tensile specimens before and after LF-HT. These micrographs were subjected to chemical attack with Weck reagent.

325 3.3 Impact and tensile properties

Figure 11.a displays the tensile engineering stress-strain curves of as-built and heat-treated 326 specimens (IF-HT and LF-HT), and the corresponding mechanical properties (σ_u , σ_u and ε_f) 327 are listed in Table 2. In the as-built condition, the tensile properties are characterized by high 328 strength but low ductility, which is typical of the martensitic microstructure of Ti64 fabricated 329 by L-PBF [21, 27, 28, 52, 59, 60]. After HT, both σ_y and σ_u show a similar decreasing trend 330 as the hardness (see Figure 4), gradually decreasing with increasing temperature. σ_u ranges 331 from 1 279±15 MPa in the as-built state to 965±11 MPa after LF-HT at 980 °C, representing 332 a 25 % reduction in tensile strength. Regarding ductility, ε_f is doubled after IF-HT at 720 °C, 333 with a further increase observed after IF-HT at 800 °C. However, for IF-HT at 860 °C and 334 920 °C, ε_f decreases compared to the previous states, and a more significant drop in ductility 335 is observed for IF-HT at 980 °C. In contrast, LF-HT samples show a superior ε_f for annealing 336 temperatures above 860 °C, with the elongation to failure reaching 18.7 ± 0.7 % for LF-HT at 337 980 °C, representing a remarkable 450 % gain in ductility compared to the as-built state. This 338 value is also 4.7 times higher than for IF-HT at the same annealing temperature. 339

The impact energy in the as-built condition is low (4.8±0.2 J); however, after HT at 720 °C, the value doubles comparatively to ε_f . With increasing annealing temperature, KV progressively increases, reaching 15.2±0.6 and 24.8±1.2 after IF-HT and LF-HT at 980 °C, respectively. Despite the scarcity of references on the impact toughness of Ti64 fabricated by L-PBF, the values found is this study are comparable to those reported in references [61–64].

345 3.4 Oxygen embrittlement and generation of strain-induced cracks

Figure 12 presents SEM-SE pictures taken at the edge of the fracture surface of broken tensile 346 samples after IF-HT at 860 °C, 920 °C, and 980 °C. Each fracture surface shows two distinct 347 zones. Just below the sample's surface, a brittle zone with an interlamellar fracture mode is 348 visible. In contrast, in the bulk of the specimen below the brittle zone, a ductile zone with the 349 presence of dimples is observed. The boundary between the brittle and ductile zones is clearly 350 distinguishable, allowing for the measurement of the brittle zone thickness. The thickness val-351 ues indicated in Figure 12 represent the average of 10 measurements taken along the perimeter 352 of one specimen for each condition. These values are in close agreement with the alpha-case 353 thicknesses estimated from microhardness profiles (see section 3.2). It is well-known that oxygen 354 can embrittle titanium alloys, leading to a shift from ductile to brittle fracture mode when the 355 oxygen content reaches 0.3 wt% or above [58, 65, 66]. Similarly, a ductile to brittle transition 356 was observed at the edge of the fracture surface of the Charpy impact specimens after IF-HT. 357 358

Figure 12: SEM-SE images captured at the edge of the fracture surface of Ti64 tensile specimens subjected to various sub-transus IF-HT.

After the tensile tests, the surface of each half-tensile specimen subjected to IF-HT exhibits a 359 high density of open cracks, homogeneously disseminated along the gauge length of the specimen. 360 As shown in Figure 13.a, these cracks are visible to the naked eye for IF-HT at 920 °C (and thus 361 for IF-HT at 980 °C). Figures 13.b and 13.c show, respectively, a metallographic cross-section of 362 the same specimen before and after chemical attack with Weck reagent. It can be observed that 363 the distance between two consecutive cracks is approximately constant along the gauge length. 364 Moreover, the depth of the cracks is almost equal to the alpha-case thickness, as highlighted 365 after the chemical attack. On the post-mortem specimen, most of the cracks are blunt after 366 367 crossing the alpha-case (see Figure 13.d). This behavior could be explained by a plastification phenomenon occurring around the curvature of the crack when it enters the ductile zone (see 368 Figure 12). 369

Figure 13: (a) Visualization of cracks on the surface of a post-mortem tensile specimen subjected to IF-HT at 920 °C for 2 hours. Visualization of cracks on a cross-section of the same specimen before (b) and after (c) chemical attack with Weck reagent. (d) Visualization of blunt cracks at the alpha-case boundary.

To investigate the formation and growth kinetics of these cracks, in-situ tensile tests were 370 conducted in the SEM chamber on small specimens cut from the surface of a block after IF-HT 371 at 860 °C (see Figure 2). The examination of the sample's surface under secondary electrons 372 was performed on the oxidized surface, which presented an alpha-case layer around 50 µm deep 373 after IF-HT (see Figure 9 and Table 2). No cracks were visible on the sample's surface before the 374 tests. During the first test, conducted by gradually increasing the applied load, the first cracks 375 were observed at a load of 400 N, corresponding to an average macroscopic stress of of 460 MPa. 376 It should be noted that this stress value is less than half of the yield stress of the material in the 377 metallurgical state obtained after HT at 860 °C for 2 h (see Figure 11 and Table 2). Similarly 378 to the observation mentioned in Figure 13.a, the cracks were uniformly distributed across the 379 observed gauge length surface of the specimen. However, these cracks were barely open and 380 detectable under SEM imaging. Another test was conducted to study the growth and opening 381 kinetics of a crack, from a macroscopic stress of 765 MPa until the specimen's failure. Figure 382 14.a presents the evolution of the crack during the tensile test. The first four pictures were taken 383 in the elastic domain, the fifth picture during the transition from elasticity to plasticity, and 384 the last four pictures were taken in the plastic domain. Figures 14.b and 14.c show respectively 385 the corresponding stress-displacement curve and the distance between the crack lips measured 386 at the middle of the SEM-SE pictures. The dots numbered in Figures 14.b and 14.c correspond 387 to the picture numbers in Figure 14.a. In the elastic domain, the crack remains almost closed, 388 with a very slight increase in the opening value from 765 MPa (dot 1) to 935 MPa (dot 4). 389 Upon transitioning to the plastic domain, the crack starts to open faster, and the growth is 390 mainly located in the plastic domain. The dotted red line plotted in Figure 14.c is a linear 391 approximation calculated between dots 5 to 8. This indicates that in the plastic domain, the 392 crack opening kinetics at the surface is almost constant for a constant displacement rate, leading 393 to a distance between the crack lips proportional to the displacement. This suggests that the 394

³⁹⁵ opening kinetics of the cracks are controlled by the applied strain. After failure (dot 9), the ³⁹⁶ crack opening shows a slight decrease that could be explained by the elastic springback of the ³⁹⁷ sample. In a nutshell, the cracks formed in the alpha-case during tensile loading appear in the ³⁹⁸ elastic domain, and their opening is primarily induced by plasticity.

399

400 4 Discussion

401 4.1 Role of annealing temperature on microstructural evolution

The microstructure consisting of 100 % entangled martensitic needles within prior β grains, 402 is consistent with observations presented in the literature [7, 25, 28, 67] for the as-built condi-403 tion. As shown in Figure 7, the as-built condition exhibits highly heterogeneous sizes of the α' 404 needles, with an average α' laths thickness of $0.34\pm0.02 \,\mu\text{m}$. After post L-PBF HT, the final mi-405 crostructure strongly depends on the annealing temperature. For all the studied temperatures, 406 martensite decomposition ($\alpha' \longrightarrow \alpha + \beta$) occurs, and β peaks are detected by XRD as presented 407 in Figure 5. As indicated in Figure 15.a, holding the alloy at high temperatures (> 700 °C) leads 408 to an increasing fraction of the β phase at equilibrium, ultimately reaching 100 % of β phase 409 at the transus temperature. Figure 15.b clearly illustrates that the higher the β phase fraction, 410 the closer the alloying element content in β to the nominal content in the alloy (10.50 at% for 411 Al and 3.46 at% for V). During slow furnace cooling, a low fraction of β matrix formed at high 412 annealing temperatures can become stabilized at room temperature (Figure 15.a), resulting in a 413 higher content of the β -stabilizing element V (Figure 15.b). Furthermore, holding the material 414 at higher annealing temperatures followed by a slow cooling rate allows a higher concentration 415 of V to diffuse from the α laths to the β matrix located along the boundaries of the α grains 416 (Figures 6.a and 6.b), leading the material to approach a closer-to-equilibrium state [32, 53, 68]. 417 Consequently, there is an increasing concentration of stabilized and retained β phase fraction at 418 room temperature with increasing annealing temperature, as shown in Figure 5.b and 6.c.419 Figure 5.b also indicates that the lattice parameter of the β phase increases with annealing tem-420 perature, as evidenced by the shift in the Bragg angle of the β (110) peak towards lower values. 421 This observation aligns with findings from other authors who studied similar sub-transus heat 422 treatments at different annealing temperatures followed by furnace cooling [29, 30]. However, 423 no specific explanation was provided in their work for this particular result. In the β phase, 424 it is known that higher vanadium content leads to a smaller lattice parameter [69, 70], due to 425 the fact that both the substitutional solid solution elements V (0.132 nm) and Al (0.143 nm)426 have smaller atomic radii than Ti (0.147 nm). Furthermore, for post L-PBF heat treatments 427 with fixed annealing temperatures but increasing holding times, Casadebaigt et al. [58] (HT 428 at 600 °C) and Cao et al. [21] (HT at 800 °C) observed a shift of the β (110) peak towards 429 higher angles, which they attributed to the solute redistribution of Al and V during prolonged 430 annealing. In the present work, the shift towards smaller angles could be attributed to an inter-431 face effect between the α and β phases. The BOR [55] governs the crystallographic orientation 432 for both the $\beta \longrightarrow \alpha$ and $\alpha \longrightarrow \beta$ transformations, resulting in a crystallographic correspon-433 dence $\{0001\}_{\alpha}$ // $\{110\}_{\beta}$ at the α/β interfaces in titanium alloys [71, 72]. To accommodate 434 the small misfit between the hcp and the bcc structures and enable the formation of a coherent 435 α/β interface, lattice distortions in the β phase have been reported in a metastable β -Ti allow 436 [73]. The results shown in Figure 6.a indicate that the higher the annealing temperature, the 437 larger the β grains along the α grain boundaries. In the case of thicker β grains, the possible 438

⁴³⁹ lattice distortions near the interface may have a lesser impact on the overall lattice structure, ⁴⁴⁰ which could explain the increase in the lattice parameter obtained by XRD for the β (110) peak. ⁴⁴¹

Figure 15: Thermo-Calc simulations performed using the Ti64 composition from Table 1 with the TCTI4 database to calculate: (a) the equilibrium mole fraction of α and β phases as a function of temperature, and (b) the equilibrium mole fraction of Al and V in α and β phases as a function of temperature.

The annealing temperature of post L-PBF HT plays a major role in the coarsening of α laths. 442 As shown in Figure 8.c, the average thickness of the α laths is maintained below 1 µm for HT at 443 720 °C and 800 °C, but an exponential coarsening evolution is observed for HT above 860 °C. 444 For low temperature HT (600 $^{\circ}C < T < 800 ^{\circ}C$), the restrained growth could be attributed 445 to an obstructing effect of the α lath boundaries. Since the β phase fraction at equilibrium 446 is limited (< 20 %, see Figure 15.a), only a few α laths transform into β , thus limiting the 447 growth of the remaining α laths. In contrast, for high-temperature HT (800 °C < T < T_{beta}), a 448 significant fraction of α laths is transformed into β (see Figure 15.a). During the furnace cooling 449 step, the $\beta \longrightarrow \alpha$ transformation is facilitated by the growth of the remaining α phase towards 450 the β matrix located along the α lath boundaries, explaining the coarsening of thickness while 451 the length of the α laths remains relatively unaffected (see scales in Figure 7). This results in 452 a significant change in the aspect ratio of the α laths. For higher annealing temperatures, the 453 reduction of interfacial energy may lead to the formation of globular grains during the coarsening 454 step, as depicted in Figure 3. It should also be noted that despite the significant increase in 455 the average α laths thickness measured for HT at higher temperatures, the distribution of the 456 α laths thickness (see Figure 8) remains highly scattered. This highlights the fact that the 457 resulting microstructure after HT is strongly influenced by the acicular microstructure obtained 458 after L-PBF fabrication, with hierarchical sizes of the α' needles [20]. 459

The influence of the utilized furnace on microstructural evolution is minimal as the thermal cycles applied are very similar between IF-HT and LF-HT (see Figure 1). Consequently, the measured β phase fraction (Figure 6.c) and average α laths thickness (Figure 8.c) show comparable results for both equipment. Only a slight reduction in α laths thickness was observed for LF-HT at high annealing temperature. The higher cooling rates achieved in LF-HT compared to IF-HT might be a contributing factor, as they allowed for a shorter time at high temperature, thereby limiting the growth of α laths [28, 68].

In conclusion, the acicular microstructure generated by L-PBF can be transformed into a 467 close-to-equilibrium microstructure through post-processing sub-transus HT. The size of the 468 resulting α laths, as well as the fraction of retained β phase, and hence the mechanical response 469 of the alloy, can be optimized by selecting an appropriate annealing temperature. The closer the 470 temperature to the transus, the higher the amount of martensite that transforms into β phase 471 at the annealing temperature and the faster the diffusion of the alloying elements. As a result, 472 closer temperatures to the transus lead to thicker α laths and higher β phase fractions. This 473 trend is particularly evident under slow cooling conditions, allowing for vanadium diffusion and 474 β phase stabilization during cooling. Based on the obtained results, the temperature range of 475 [860 °C; 920 °C] appears to be suitable for controlling the trade-off between α laths size and β 476 phase fraction, thereby achieving a favorable compromise between strength and ductility. 477

478 4.2 Role of annealing temperature on alpha-case formation

Unlike the microstructural evolution, the choice of the heating furnace plays a major role 479 in alpha-case formation. As shown in Figures 16.a and 16.b, no alpha-case was revealed by 480 chemical etching after LF-HT, while an alpha-case layer whose depth increases with increasing 481 temperatures was revealed after IF-HT. Figures 1.a and 1.b illustrate the significant difference 482 in vacuum pressure attained in the industrial furnace ($< 5 \times 10^{-4}$ mbar, i.e. secondary vacuum) 483 compared to the laboratory furnace ($< 5 \times 10^{-2}$ mbar, i.e. primary vacuum). This indicates 484 that the furnace atmosphere, although crucial for controlling the oxidation kinetics of the Ti64 485 alloy at high temperatures [74, 75], is not the sole factor in preventing alpha-case formation 486 on the components. The differences observed between IF-HT and LF-HT can be attributed to 487 various factors, including the volumetric dimensions of the chambers and the materials used for 488 insulation and heating elements. The industrial furnace has a much larger effective capacity 489 (0.25 m^3) compared to the laboratory furnace $(5 \times 10^{-3} \text{ m}^3)$, which may make maintaining air-490 tightness more challenging in the former. Additionally, the use of fiber/wool insulation can 491 influence oxidation during HT (degassing), thus facilitating the formation of alpha-case. 492

The results presented in Figures 9 (metallography with Weck reagent), 10 (microhardness profiles), 12 (brittle layer at the edge of the rupture surface), and 13 (cracks at the surface of tensile specimens) demonstrate that the impact of the alpha-case layer is measurable through various characterization techniques. Hence, it is possible to evaluate, from each technique, the thickness of the sub-surface layer of material affected by the presence of a higher oxygen concentration than the bulk material. The thicknesses of this so-called Oxygen Affected Zones (OAZ) measured from the aforementioned results are plotted in Figure 16.a. For the five IF-HT temperatures, the OAZ measured by different techniques are comparable, indicating that the presence of oxygen is responsible for the change in hardness and consequently the shift in the fracture mode from ductile to brittle near the surface.

The diffusion of oxygen in titanium and its alloys tends to follow parabolic kinetics [41, 76, 77]. Therefore, it can be modeled using the solution of Fick's second law in a semi-infinite solid (equation 1). This model assumes a constant concentration C_S at the surface, a constant initial concentration C_0 in the bulk of the metal, and a constant diffusion coefficient D under isothermal conditions [38, 58, 77, 78]:

$$C(x,t) = C_0 + (C_S - C_0) \times \left(1 - erf\left(\frac{x}{2\sqrt{Dt}}\right)\right)$$
(1)

Considering that the OAZ depth values are measured at a distance from the surface where the 508 oxygen concentration C(OAZ, 2h) is close to the bulk concentration C_0 , the criterion OAZ =509 $4 \times \sqrt{D \times 2h}$ was chosen. This criterion, according to equation 1, yields a ratio (C(x,t) - t)510 $(C_0)/(C_S - C_0) = 1 - erf(2) \approx 0,005$. Using this criterion, the values of D for the five an-511 nealing temperatures were calculated based on the OAZ measurements obtained from different 512 techniques, as shown in Figure 16.a. The resulting data are plotted on the Arrhenius diagram 513 displayed in Figure 16.b and were fitted to obtain the pre-exponential factor D_0 and the activa-514 tion energy Q for the diffusion of oxygen in L-PBF Ti64, using the following equation: 515

$$D(T) = D_0 \times \exp\left(\frac{-Q}{RT}\right) \tag{2}$$

Figure 16: (a) Evaluation of the thickness of the Oxygen Affected Zone (OAZ) using various techniques, and (b) Arrhenius plot showing the oxygen diffusion coefficients in Ti64 obtained in this study compared with data from references [79] and [58].

The values D_0 and Q obtained from the fits using the OAZ data measured with different techniques are listed in Table 3. As indicated by the blue and red straight lines in Figure 16.b, the obtained values are close to those reported by Liu and Welsch for the diffusivity of oxygen in α pure titanium [79], and even closer to those found by Casadebaigt et al. for the diffusivity of oxygen in Ti64 fabricated by additive manufacturing (L-PBF and Electron Beam Melting) [58].

Measurement technique	$D_0 \ ({ m m}^2 \ { m s}^{-1})$	$Q \; (kJ \; mol^{-1})$

Table 3: Pre-exponential factors D_0 and activation energies Q calculated from the fitted data in Figure 16.b.

As direct measurements of the oxygen concentration profile were not established in this work, it 522 is assumed that some of the indirect measurement techniques proposed may lead to an under-523 estimation or an overestimation of the diffusivity of oxygen in L-PBF Ti64. Consequently, to 524 simulate oxygen concentration profiles for the IF-HT conditions, the mean values of the diffu-525 sion coefficient parameters D_0 and Q were considered (see Table 3). The parameter C_0 is fixed 526 equal to 0.48 at% (0.17 wt%), which corresponds to the bulk concentration of the Ti64 printed 527 material used in this work and was measured by infrared absorption of combustion gases with 528 a LECO TC-436 (O,N) analyzer. The parameter C_S is fixed at 33 at%, which is the solubility 529 limit of oxygen in the α phase of titanium [38]. Using these parameters in equation 1, the oxygen 530 concentration profiles in the sub-surface of IF-HT samples are simulated in Figure 17.a. The 531 Oxygen Diffusion Zones (ODZ) indicated by black cross marks are defined as the depths where 532 an oxygen concentration of 0.6 at% ($\approx 0.2 \text{ wt\%}$) is reached. This value represents the upper limit 533 of oxygen content in ASTM grade 5 Ti64. The vertical dashed lines indicate the depths where 534 an oxygen concentration of 1 at% is reached. This value is referred to as the oxygen content 535 above which the ductility of Ti64 decreases drastically [80, 81]. Interestingly, the depth values 536 located at the positions of the dashed lines (corresponding to 1 at% oxygen concentration) are 537 very similar to the thicknesses of the brittle layer measured on tensile specimens (see Figures 12 538 and 16.a). This suggests that the transition from ductile to brittle behavior is likely to occur 539 for oxygen concentrations as low as around 1 at%, which is consistent with other literature 540 findings [58, 80, 82]. The hardness of titanium and its alloys is sensitive to small variations in 541 oxygen content [39, 66, 83, 84]. Therefore, the simulated oxygen concentrations displayed in 542 Figure 17 can be compared to the microhardness values given in Figure 10. The evolution of 543 hardness with oxygen content follows a parabolic law: Vaché and Monceau highlighted that a 544

linear relationship exists between hardness values and the square root of oxygen atomic percent 545 values for commercially pure titanium and Ti-6242 α titanium alloy [41]. Figure 18 shows that 546 such a relationship is also found for L-PBF Ti64, with consistent coefficients of determination 547 R^2 obtained. For the three linear regressions of the microhardness values obtained from IF-548 HT samples annealed at 860 °C, 920 °C and 980 °C, the slopes of the fitted relations vary. 549 This feature indicates that the microstructural evolution needs to be taken into account when 550 evaluating oxygen hardening in Ti64 alloy. Finally, the linear regressions plotted in Figure 18 551 support the validity of the oxygen concentration simulation (Figure 17) and hence the reliabil-552 ity of the experimental coefficients found in this study for the diffusion of oxygen in L-PBF Ti64. 553 554

Figure 17: Simulated oxygen concentrations in the sub-surface of IF-HT samples obtained using equation 1. The vertical dash lines indicate the depths where an oxygen concentration of 1 at% is reached.

Figure 18: Microhardness values measured in the sub-surface of Ti64 samples subjected to various LF-HT shown in Figure 10, plotted as a function of the square root of the simulated oxygen atomic concentration displayed in Figure 17.

4.3 Impact of microstructural evolution on mechanical properties

Average tensile properties evaluated from stress-strain curves of vertically built IF-HT and 556 LF-HT samples (Figure 11.a) are plotted in Figure 19. The evolution of strength (σ_y and σ_u 557 in Figure 19.a) and hardness properties $(HV_{1kg} \text{ in Figure 4})$ is in good agreement with the 558 microstructural characterization performed on both IF-HT and LF-HT samples. As mentioned 559 in section 4.1, the microstructure (prior β grains, α laths thickness, β phase fraction) obtained 560 after IF-HT and LF-HT conditions is very similar, resulting in similar properties as well. Only a 561 slight increase in HV_{1kq} and σ_y is noticed for LF-HT samples at higher annealing temperatures 562 compared to IF-HT samples. This observation could be attributed to the higher cooling rates 563 obtained for LF-HT samples, leading to a slightly finer microstructure. The hardness and σ_y of 564 Ti64 primarily depend on the characteristic sizes of the microstructure, especially the α laths 565 thickness [4, 28, 85]. As shown in Figure 20, a clear correlation can be established between the 566 yield stress and/or the hardness with the inverse square root of the measured average apparent 567 thickness of the α laths (d from Figure 8). This reveals that σ_u (hence HV) follows a Hall-Petch 568 relationship with the α laths thickness. Similar relationships have been established in other 569 studies for Ti64 fabricated by L-PBF [21, 68, 86], as well as with other fabrication routines [87]. 570 From this plot and using the indicated coefficients obtained in Figure 20, it would be possible to 571 estimate the characteristic size of the α laths from a simple hardness measurement and forecast 572 an expected yield stress value at the same time. 573

The σ_u measured for LF-HT samples at higher annealing temperatures are greater than those measured for IF-HT samples. As shown in the tensile stress-strain curves in Figure 11.a, the strain hardening is limited for samples after IF-HT at 920 °C and 980 °C, as the highest measured stress values (hence σ_u) are located close to the fracture zone.

Previous studies focusing on the effects of sub-transus HT on the tensile behavior of L-PBF 578 Ti64 parts have often reported that the closer the temperature to the transus, the higher the 579 elongation to failure [30, 49, 52, 68]. This behavior is observed for LF-HT samples in Figure 580 19.b. Very high elongations to failure, comparable to those of wrought Ti64, are obtained for the 581 highest sub-transus LF-HT temperatures. Furthermore, even though the samples in the present 582 study were tested with their raw surface state, the elongation values are similar to those obtained 583 with machined Ti64 L-PBF samples [88]. In contrast, the ε_f of IF-HT samples decreases for 584 annealing temperatures of 860 °C and above. The main highlighted difference between IF-HT 585 and LF-HT microstructures is the presence of an alpha-case at the sub-surface. Therefore, it 586 is expected from these results that the alpha-case layer plays a major role in decreasing the 587 ductility of the Ti64 alloy. This result emphasizes the importance of considering the heating 588 environment when designing post L-PBF HT for Ti64 alloy. The role of alpha-case thickness on 589 the ductility drop is further discussed in section 4.4 hereafter. 590

The impact properties measured on Charpy V-notch specimens (Figure 11.b and table 19) show a similar trend in elongation to failure for IF-HT and LF-HT below 860 °C. However, contrary to ductility, the resilience of the material after IF-HT is slightly improved at annealing temperatures of 860 °C and above. Nevertheless, the values obtained for samples after LF-HT at 860 °C and above are significantly better than the ones obtained after IF-HT. The improved resilience of

⁵⁹⁶ LF-HT samples aligns with the coarsening of α laths and the increased β phase fraction, as the ⁵⁹⁷ impact toughness of Ti64 alloy is primarily influenced by the size of microstructural elements ⁵⁹⁸ that cause bifurcation of the crack propagation path [89, 90]. However, the highest impact ⁵⁹⁹ toughness obtained in this work (24.8±1.2 J) is still lower than the $\approx 30 - 40$ J impact tough-⁶⁰⁰ ness measured for Ti64 fabricated using conventional processes that exhibit a typical lamellar, ⁶⁰¹ equiaxed, or bimodal microstructure [63, 89–91].

602

Figure 19: Evolution of tensile properties of the vertically built samples in the as-built condition and subjected to various IF-HT and LF-HT: (a) Yield stress σ_y and ultimate tensile strenght σ_u , (b) Elongation to failure ε_f .

Figure 20: Evolution of the measured yield stress and hardness as a function of the inverse square root of the measured average apparent thickness of the α laths.

603 4.4 Impact of alpha-case depth on embrittlement

Figures 13 indicate that cracks are generated along the gauge length surface of the sample 604 during the tensile test and propagate in a brittle manner (see Figure 12) across the alpha-case 605 thickness, which corresponds to the area with the highest oxygen concentration in the material 606 (see Figure 17). As shown in Figure 19.b, the presence of an alpha-case thickness of approxi-607 mately $10 - 25 \,\mu\text{m}$ (IF-HT at 720 °C and 800 °C) does not seem to significantly influence the 608 elongation to failure for 3 mm thick tensile samples. However, for alpha-case thicknesses of 609 approximately 50 µm (IF-HT at 860 °C), ε_f is slightly lower compared to the LF-HT sample 610 without alpha-case. Finally, alpha-case thicknesses of approximately $\approx 100 - 200 \ \mu m$ (IF-HT 611 at 920 °C and 980 °C), which cause the presence of deeper strain-induced cracks, are extremely 612 detrimental to the ductility of the sample: ε_f is respectively half and four times lower than for 613 similar samples without alpha-case. 614

From the results presented in this work, it is, however, difficult to understand the mechanisms 615 explaining the impact of the deeper strain-induced cracks on ductility. A first hypothesis is 616 that the stress concentration at the crack tips is high enough to initiate crack propagation in 617 the bulk material and lead to premature failure starting from the surface. However, as most of 618 the cracks presented in Figure 13 are blunt and do not propagate beyond the alpha-case, this 619 assumption is questionable. A second hypothesis is that the damage is initiated in the bulk, but 620 because of the stress concentration at the crack tips, the material's ability to plastically deform 621 is drastically reduced, leading to sample fracture with little plastic strain necessary. To verify 622 the validity of either hypothesis, *in situ* tensile tests combined with X-ray tomography could be 623 performed to determine whether the damage initiates at the crack tips or in the bulk [92]. 624

The impact energy values obtained suggest that for IF-HT at the highest annealing temper-625 atures, the brittle layer limits the length of the crack propagation path and, therefore, the 626 material's ability to absorb energy. However, the impact toughness of the material is less af-627 fected by oxygen embrittlement compared to the achievable ductility under tensile loading: the 628 IF-HT condition with the worst f exhibits the best KV in this study. This result could be 629 explained by a "size-effect" of the sample: the $\approx 200 \ \mu m$ alpha-case for IF-HT at 980 °C affects 630 only 5 % of the 8 mm thick normalized Charpy V-notch impact samples, while it affects more 631 than 13 % of the 3 mm thick dog-bone shape tensile specimens. Furthermore, it is generally 632 reported that fracture toughness is a combination of ductility and strength of the material. This 633 illustrates that alpha-case embrittlement does not show the same effects on the material prop-634 erties depending on the loading mode. 635

One of the key findings of this study is the evidence of visible cracks under SEM in the alphacase layer of a tensile sample loaded in the elastic domain (Figure 14). These cracks started to be detectable at tensile stress values that are half the measured yield stress of the material. This result suggests that, besides the ductility decrease for the highest annealing temperatures, alpha-case embrittlement could be highly detrimental to the fatigue performance of Ti64 alloy fabricated by L-PBF and subjected to an industrial post-processing HT with a partially contained oxidizing environment.

643 5 Conclusions

In this study, post Laser Powder Bed Fusion process (L-PBF) heat-treatments (HT) on Ti-645 6Al-4V (Ti64) samples with various sub-transus annealing temperatures were performed. To 646 significantly modify the atmo- sphere, the HT were conducted using an industrial furnace (IF-647 HT conditions) and a laboratory furnace (LF-HT conditions). The objective of this study was to 648 investigate the effects of microstructural evolution and alpha-case formation on the mechanical 649 properties of L-PBF Ti64 parts that will not undergo any machining after fabrication. The 650 following conclusions were drawn from this work:

- The as-built microstructure consists of entangled α' martensitic needles that form within prior β grains during the rapid cooling of the L-PBF process. Sub-transus HT for 2 hours between 720 °C and 980 °C, followed by slow furnace cooling, results in the decomposition of martensite into $\alpha + \beta$ equilibrium phases while preserving the prior β grain structure. Quantitative measurements revealed that the higher the annealing temperature, the greater the β phase fraction and the growth of α grains. The bulk microstructures obtained for IF-HT and LF-HT were nearly identical.
- The IF-HT samples displayed a notable increase in alpha-case thickness with higher annealing temperatures, resulting in significantly elevated surface hardness. On the contrary, no alpha-case formation was observed in the LF-HT samples. Oxygen concentration exceeding 1 at% led to a transition from ductile to brittle fracture mode, causing the appearance of a brittle layer on the edge of the fracture surface in the mechanical specimens. Tensile samples exhibited crack formation along the gauge length surface, which propagated through the alpha-case.
- In the as-built condition, the tensile properties exhibit very high strength but poor ductil-665 ity. The microstructural evolution during sub-transus HT helps achieve a balance between 666 strength and ductility, with the yield stress being governed by the thickness of the α laths 667 through the Hall-Petch mechanism. However, the ductility of IF-HT samples decreases 668 significantly for alpha-case depths \geq 50 µm. For IF-HT at 800 °C for 2 h, a favorable 669 compromise is achieved, resulting in a strong material ($\sigma_y > 1$ 000 MPa) with good duc-670 tility ($\varepsilon > 10$ %) when the tensile load is parallel to the building direction, with minimal 671 effects of the approximately 25 µm alpha-case on the tensile properties. On the other hand, 672 without any alpha-case, the ductility can be further increased with higher temperatures, 673 as demonstrated in LF-HT samples. The alloy exhibits a similar evolution in terms of 674 ductility and impact toughness. 675
- Cracks formed at the sample surface during the tensile test are "strain-induced", and their
 opening rate at the surface is primarily controlled by the level of plastic strain. However, *in situ* investigations have revealed that these cracks actually initiate in the elastic domain,
 even at stress levels lower than half the yield stress. Therefore, further research should be
 undertaken to explore the potential influence of the alpha-case on the fatigue behavior of
 Ti64 alloy fabricated using L-PBF.

Data availability

The raw/processed data required to reproduce these findings cannot be shared at this time as the data also forms part of an ongoing study.

Declaration of Competing Interest

The authors declare that they have no known competing financial interests or personal relationships that could have appeared to influence the work reported in this paper.

Acknowledgments

This work, conducted at LGF and MATEIS laboratories, falls within the framework of the AEROPRINT project, which received support from the Auvergne-Rhône-Alpes Region and the the company Dassault Aviation, France. The authors are grateful for their financial support and extend special thanks to the project team at the Argonay production site for fabricating the samples used in this study. Additionally, the authors would like to acknowledge the valuable contributions of Pauline Chanin-Lambert and Maryline Mondon for their assistance with the laboratory furnace setup, Nathalie Peillon for conducting XRD measurements, Séverine Girard-Insardi for supervising tensile and impact tests, Gilles Blanc for overseeing metallographic preparation, and Florian Steinhilber and Amélie Larguier for their involvement during in situ tensile tests. The authors also express their appreciation to David Piot and Guillaume Kermouche for engaging in numerous fruitful discussions.
