## 50 51 Abstract

52 A novel extrinsic measurement of the particle surface distribution in a carbon black  
53 filled elastomer via nanoindentation is developed. This method is based on the mea-  
54 surement of the contact stiffness obtained from the Continuous Stiffness Measurement  
55  
56  
57  
58

(CSM) mode. The proposed tip-particle model is held by two main hypotheses: the particles do not deform significantly during indentation so that only the elastomer matrix elastically deforms; particles are physically bounded with the surrounding matrix. Therefore, when the tip enters in contact with a particle, the latter becomes a hard extension of the tip, able to deform the elastomer matrix. Finally, the evolution of measured contact stiffness is directly related to the increase of contact area between the tip-particles set and the elastomer matrix. The proposed model is validated through a numerical and an experimental study. Moreover, an evaluation of the measurements bias allows to correct the particle surface distribution. A good agreement is found between the distribution measured from TEM observations and nanoindentation measurements.

Nanoindentation, Particles distribution, Elastomer, Heterogeneities, Stiffness

## 1 Introduction

Characterization of particles, aggregates or agglomerates dispersion and size distribution in a polymer matrix is of primary interest for the reinforced polymer community. Indeed, these aspects influence directly the mechanical (conservative modulus, hardness, ...),<sup>1-4</sup> electrical (conductivity)<sup>5</sup> or physical (glass transition and melting temperatures)<sup>6</sup> properties.

In the case of fluoroelastomers (FKM), a reinforcement of the matrix by nanoparticles or carbon black enhances their thermal resistance. This improvement allows the use of FKM elastomers in petrochemical industry, automotive, aeronautics and aerospace as seals, gaskets or O-rings used in extreme temperatures.<sup>7-9</sup>

Effects of the particles, aggregates or agglomerates can be characterized at different scales, from discrete to homogenized analysis. Therefore, several methods can be used to

1  
2  
3 characterize, with high resolution, dispersion and size distribution of hard particles in a soft  
4 media:<sup>10</sup>  
5  
6

7 Transmission Electron Microscopy (TEM) is clearly the most accurate characterization  
8 method<sup>11</sup> with a resolution down to 0.05 nm. However, it requires the preparation of thin  
9 foils which is a difficult and expensive task with such soft media: Its use is therefore strongly  
10 limited. Small Angle X-Ray Scattering (SAXS) allows for the measurement of nanoparti-  
11 cles size over several nanometers length scale in an easier way<sup>12-14</sup> but it remains a global  
12 measurement technique and requires some mathematical inversion models and hypotheses  
13 on nanoparticle shape to estimate the nanoparticle size distribution. Also, Dynamic Light  
14 Scattering (DLS) allows to measure particles sizes ranging from 2 nm to 2  $\mu\text{m}$ <sup>15</sup> with ap-  
15 plications to translucent materials. Regarding mechanical measurement, Atomic Force Mi-  
16 croscopy (AFM)<sup>16</sup> can evaluate local stiffness gradient with a spatial resolution down to  
17 15 nm. Dispersion of particles can also be assessed by conductive probe AFM in contact  
18 mode<sup>5</sup> at the nanometric scale.

31 Nanoindentation results, for this kind of materials, are mainly interpreted as for homog-  
32 enized solids with an intrinsic Indentation Size Effect (ISE)<sup>2</sup> related to the presence of hard  
33 bodies in the soft matrix for 100 nm to some microns. Yet, no attempt has been done to  
34 link the change in mechanical properties with the size and distribution of the concerned hard  
35 bodies. It is proposed here, with a simple model named "tip-particle", to bridge the gap  
36 between a fully discrete and a homogenized analysis by considering the participation of each  
37 particle (or aggregate and agglomerate) to the change in measured mechanical properties –  
38 i.e. contact stiffness.

45  
46

47 The proposed tip-particle model is held by two main hypotheses: the particles do not  
48 deform significantly during indentation so that only the elastomer matrix elastically deforms  
49 and the particles are physically bounded with the surrounding matrix. Therefore, when the  
50 tip enters in contact with a particle, the latter becomes a hard extension of the tip, able to  
51 deform the elastomer matrix. Finally, the evolution of measured contact stiffness is directly

3 related to the increase of contact area between the tip-particles set and the elastomer matrix.

4  
5 First, experimental evidences of a carbon black-filled fluoroelastomer heterogeneity are  
6 detailed based on TEM observations and nanoindentation experiments. Then, a tip-particle  
7 model is proposed in order to better understand the contribution of the carbon black ag-  
8 gregates to the contact stiffness evolution during nanoindentation. This model is used to  
9 deduce from nanoindentation experiments, the distribution of particles' projected area in  
10 the carbon black-filled fluoroelastomer. Finally, the model is challenged and discussed with  
11 numerical simulation based on TEM observations and nanoindentation experiments.

### 22 **2.1 Material**

23  
24  
25 The studied material is a fluoroelastomer vulcanized with peroxide. Figure 1 shows a TEM  
26 image of FKM elastomer composed of a rubber matrix (light gray), small and well-dispersed  
27 carbon black agglomerates with diameter between 300 and 800 nm (black) and silicon agglom-  
28 erates with typical size of several tens of nanometers (intermediate gray). White spots are  
29 voids in the sample which correspond to carbon black aggregates removed during the TEM  
30 specimen preparation. The composite material's glassy transition temperature, measured by  
31 Differential Scanning Calorimetry (DSC), is -17 °C. The conservative modulus, measured by  
32 Dynamic Mechanical Analysis (DMA) at 1 Hz and 0.01 % strain, is 15 MPa. For compar-  
33 ison, the Young modulus of carbon black nanoparticles have been measured around 9 GPa  
34 by nano-compression.<sup>17</sup>

## 2.2 Nanoindentation experiments

Nanoindentation experiments were performed with a Nanoindenter SA2<sup>®</sup> (Keysight Technologies, Santa Rosa, California) with a Dynamic Contact Module (DCM<sup>®</sup>) head that allows for very accurate measurements at low load and displacement. The indentation set-up is load-controlled with a maximum force of 10 mN and a resolution of 1 nN. Displacement is measured with a resolution of 0.2 pm.

Constant strain rate loadings have been performed on the carbon black-filled fluoroelastomer with a typical strain rate of  $\dot{h}/h = 0.02 \text{ s}^{-1}$  and a maximum penetration depth of 1500 nm. The Berkovich diamond tip, used for this study, have a height defect of 6 nm, as determined in a previous study.<sup>18</sup> Constant strain rate experiments were reproduced ten times at different locations to exploit statistically the data. The Continuous Stiffness Measurement (CSM) module was used with an amplitude of 4 nm at 75 Hz to measure the stiffness as a function of time.

It has been assessed by several authors that contact area is proportional to the contact stiffness as long as the materials' modulus is not indentation depth-dependent. Hence, the

1  
2  
3 following relation is used<sup>19,20</sup> :  
4  
5

$$S(\omega) = 2E_c'^*(\omega)\sqrt{\frac{A_c}{\pi}} \quad (1)$$

6  
7  
8  
9

10 Where  $S(\omega)$  and  $E_c'^*(\omega)$  are the contact stiffness and the reduced contact modulus mea-  
11 sured at a given frequency  $\omega$ , and  $A_c$  is the contact area.  
12  
13

14 The evolution of contact stiffness with contact depth is represented in figure 1b. The-  
15oretically, for a homogeneous material, the contact stiffness is directly proportional to the  
16 contact depth. However, when indenting a heterogeneous material, this relation is no longer  
17 valid and abnormal contact stiffness evolutions are measured (see figure 1b).  
18  
19  
20  
21  
22

## 23 2.3 Tip-particle model

24  
25

26 The tip-particle model is based on a simple hypothesis which states that all the deformation  
27 in the material is supported by the elastomer matrix. Hence, carbon black aggregates, which  
28 are two orders of magnitude stiffer and harder than the elastomer matrix, as described in  
29 section 2.1, do not significantly deform during indentation. Also, the mean pressure under  
30 the tip  $p_m = F/A_c$ , with  $F$  the load on sample and  $A_c$  the contact area does not exceed  
31 100 MPa at shallow depth and goes down to around 0.8 MPa above 150 nm depth. This is  
32 significantly lower than the hardness of the carbon black aggregates and makes us confident  
33 that the latter should not be crushed or broken under the tip. As a consequence, when the  
34 diamond tip enters in contact with an aggregate, the latter becomes a hard extension of the  
35 tip capable to deform the elastomer matrix underneath. Furthermore, when an aggregate  
36 enters in contact with the tip, the contact area extension induces a sudden increase in contact  
37 stiffness. These events have been reported experimentally and are coherent with the present  
38 model.  
39  
40  
41

52 The hypotheses of the model are listed below:  
53  
54  
55  
56  
57  
58  
59  
60

- All the deformation in the material is supported by the elastomer matrix.
- Particles do not significantly deform during indentation.
- Particles are physically bounded to the surrounding matrix.
- Particles are not in contact with each other.
- The adhesion between the tip, the particles and the matrix is negligible.
- An abnormal increase of the stiffness is attributed to a single particle entering in contact with the tip.

Figure 2: Example of the tip-particle model, with the black particles corresponding to carbon black aggregates and the gray part corresponding to the elastomer matrix. The green parts represent the area of the Berkovich tip and the particles in contact with the tip.

Figure 2 displays the tip-particle model basic principle, with the Berkovich tip in contact with the three particles highlighted in green.

## 2.4 Distribution of particles' projected area

The particle projected area distribution is extracted from the tip-particle model considering each stiffness jump as the combined participations of the homogeneous increase of contact area and the apparition of a particle in the contact. Hence, the total increment area  $\Delta A_c$  – i.e. increment area from the indenter with the particles in contact – can be calculated from equation 1 as a function of the jump stiffness amplitude  $\Delta S$  and the contact stiffness  $S$  just before the jump.

$$\Delta A_c = \frac{\pi}{4E_c'^{*2}} (2S\Delta S + \Delta S^2) \quad (2)$$

The projected area of the detected particle is written as:

$$A_{part} = \Delta A_c - \xi \Delta A_{c, hom} \quad (3)$$

$$\Delta A_{c, hom} = \frac{\pi}{4E_c'^{*2}} (S_{he}^2 - S_{hb}^2) \quad (4)$$

Where  $A_{part}$  is the particle size and  $\Delta A_{c, hom}$  is the homogeneous increase of the contact considering only fluoroelastomer matrix. Moreover,  $S_{hb}$  and  $S_{he}$  are the stiffnesses in the case of a homogeneous material at the beginning and at the end of the jump, respectively. These stiffnesses are calculated with a linear relationship between  $S$  and  $h_c$  such as  $S_h = \frac{2E_c'^{*}}{\tan(\beta)} h_c$ , with  $h_c$  the contact depth, calculated from the Oliver and Pharr model,<sup>19,21</sup> and  $\beta = 19.68^\circ$  the inclined face angle of the Berkovich equivalent conical tip. In equation 3, the portion of indenter area removed from the total increment area is noted  $\xi$ . The meaning of  $\xi$  is illustrated on figure 3.a where, after an increment, the indenter touches a new particle (in light green). This new particle implies an increase in the stiffness measurement characterized by a segment in figure 3.b.  $\xi$  modifies the portion of the jump attributable to the new particle such as, for  $\xi = 1$ , 100 % of the new indenter perimeter is removed (see figure 3.c). This

leads to a correct estimation of the particle area if no other particles are already in contact, but it leads to underestimation of its size otherwise. For  $\xi = 0$ , all the area responsible for the stiffness jump amplitude is associated to the particle (see figure 3.d). Here again, it is not right since a part of the stiffness jump amplitude is due to the increase of the indent size. Hence, the portion of stiffness jump attributable to one new particle is dependent on the number of particles already in contact at the periphery of the indenter. An estimation of  $\xi$  will be performed based on numerical simulation in the results section.

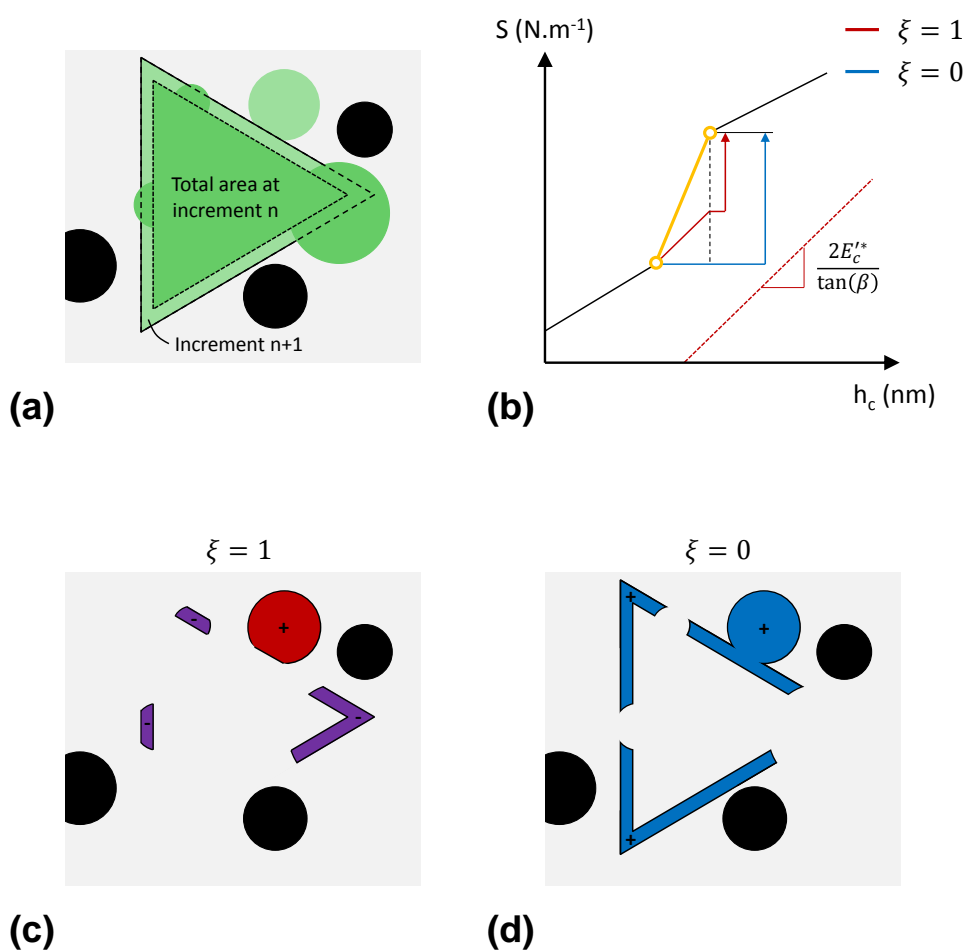

Figure 3: Schematic representation of an indent entering in contact with particles (a) and the different ways of considering the particle area: (c) residual area of the particle considering  $\xi = 1$  ; (d) residual area of the particle considering  $\xi = 0$  and (b) impact on the stiffness jump portion attributable to the particle.

## 2.5 Detection limitations due to the loading

If we consider that a stiffness jump is attributed to a single particle – i.e. without considering the homogeneous increase of the contact size during the jump,  $\xi = 0$  – the range of detectable particle size can be derived from the expression 2. With a minimum stiffness amplitude detection  $\Delta S_{min}$  in the equation 2, one can describe the minimum detectable area  $A_{part} = \Delta A_c$  as a function of contact stiffness  $S$  – i.e. indentation depth. The following developments are written as a function of the total increment area  $\Delta A_c$  for sake of uniformity with equation 2.

Then, considering the maximum stiffness attained during the experiment  $S_{max}$ , the detection limits for a given particle size are known. In other words, the minimum particle area detectable is a function of the contact area between the tip and the matrix – i.e. larger is the tip-elastomer contact size, higher is the minimum detectable particle area.

Figure 4 displays a diagram representing the detection space as a function of the particle size  $\Delta A_c$ . This space is delimited by equation 5 for  $\Delta A_c \in [\Delta A_{c, min}, \Delta A_{c, lim}]$  and by  $S_{max}$  for  $\Delta A_c \in [\Delta A_{c, lim}, +\infty)$ .

$$S(\Delta A_c) = \frac{2E_c'^2}{\pi \Delta S_{min}} \Delta A_c - \frac{\Delta S_{min}}{2} \quad (5)$$

The different detection zones are the following:

- The first zone is delimited by  $\Delta A_c \in [0, \Delta A_{c, min}[$  and corresponds to particle areas which cannot be detected due to the lower stiffness detection  $S_{min}$  ;
- The second zone is delimited by  $\Delta A_c \in [\Delta A_{c, min}, \Delta A_{c, lim}[$  where the particles can be partially detected during the whole loading ;
- Finally, the third zone, delimited by  $\Delta A_c \in [\Delta A_{c, lim}, +\infty)$ , where the particles are fully detected. Hence, for particles areas greater than  $\Delta A_{c, lim}$ , no underestimation of their occurrences is due to the loading procedure.

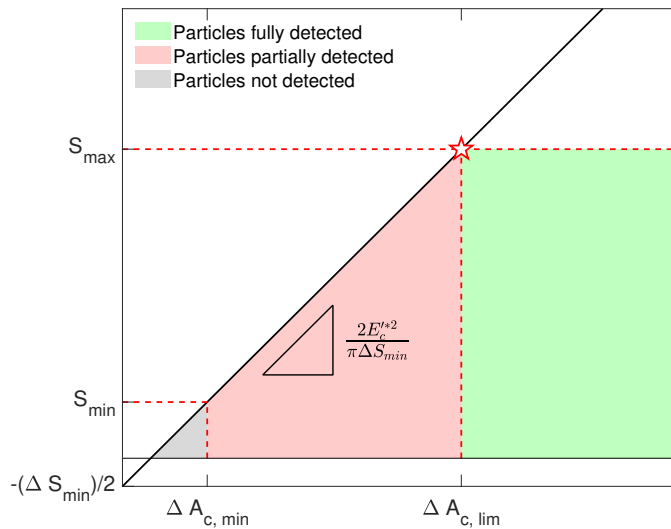

Figure 4: Detection space as a function of the particle size considered and of the stiffness parameters  $\Delta S_{min}$  and  $S_{max}$ .

Therefore, the smallest particle detectable during a whole loading  $\Delta A_{c, lim}$  is expressed from equation 2 such as:

$$\Delta A_{c, lim} = \frac{\pi}{2E_c'^{*2}} \left[ S_{max} \Delta S_{min} + \frac{\Delta S_{min}^2}{2} \right] \quad (6)$$

In the case where the particles size are included between  $\Delta A_{c, min}$  and  $\Delta A_{c, lim}$ , the same equation can be written by replacing  $S_{max}$  by  $S$ , with  $S < S_{max}$ . This relates the maximum stiffness  $S$  at which the considered particle area  $\Delta A_c$  is detected. By extension, the maximum tip-elastomer contact area  $A_c(S)$  is related to the considered particle area  $\Delta A_c$ .

This means that for each particle area  $\Delta A_c < \Delta A_{c, lim}$  the associated maximum tip-elastomer contact area  $A_c(S)$  is lower than the contact at the end of loading  $A_c(S_{max})$ . Therefore, the concerned particle densities are underestimated because they are calculated based on a lower probed area.

Considering this, a correction can be applied to the measured particle densities with the hypothesis of a homogeneous distribution of the particles within the total probed area.

The measurement bias  $\alpha$  is expressed as the ratio of the maximum tip-elastomer area  $A_c(S)$  enabling the detection of a given particle area  $\Delta A_c < \Delta A_{c, lim}$  over the final contact area  $A_c(S_{max})$ . Therefore, the measurement bias  $\alpha$  is proportional to the square of the stiffness  $S$ , as written in equation 7. If  $\alpha = 1$ , there is no bias and if  $\alpha < 1$  there is one.

$$\alpha = \frac{A_c(S)}{A_c(S_{max})} = \frac{S^2}{S_{max}^2} \quad (7)$$

Developing equation 7 with equation 5 as a function of particle area  $\Delta A_c$  leads to a polynomial of the second order:

$$\alpha = \left[ \left( \frac{2E_c'^{*2}}{\pi \Delta S_{min}} \right)^2 \Delta A_c^2 - \frac{2E_c'^{*2}}{\pi} \Delta A_c + \frac{\Delta S_{min}^2}{4} \right] \frac{1}{S_{max}^2} \quad (8)$$

Equation 8 expresses the measurement bias for each particle area lower than  $\Delta A_{c, lim}$  as a function of  $S_{max}$  and  $\Delta S_{min}$ . To correct a distribution of particle densities, represented as a histogram, an average of equation 8 must be done for each interval of particle size – i.e.  $\Delta A_c \in [\Delta A_c(i), \Delta A_c(i + 1)]$ . This equivalent measurement bias is written  $\alpha_{equ}$ .

Equation 8 is valid for  $S(\Delta A_c) < S_{max}$ . When  $S(\Delta A_c) \geq S_{max}$ ,  $\alpha = \alpha_{equ} = 1$ . Figure 5 displays  $\alpha$  from equations 8 and  $\alpha_{equ}$  as a function of  $\Delta A_c$ .

From these developments, the correction applied to the number of detected particles as a function of their sizes  $N_{exp}(\Delta A_c)$  is expressed as follow:

$$N_{cor}(\Delta A_c) = \frac{N_{exp}(\Delta A_c)}{\alpha_{equ}} \quad (9)$$

With  $N_{cor}$  the number of particles corrected and  $N_{exp}$  the number of particles detected experimentally. This model prediction will be assessed in the following by means of numerical and experimental results.

Figure 5: Measurement bias  $\alpha$  and  $\alpha_{equ}$ , expressed by equation 8 and from its interval average, respectively, as a function of particle area  $\Delta A_c$ .

### 3 Results and discussion

#### 3.1 Experimental stiffness measurements

As it has been described in previous section, stiffness measurements have been performed with the continuous stiffness measurement module available on the DCM<sup>®</sup> nanoindenter head. Contact stiffness is measured by oscillating the tip at targeted amplitude and frequency – i.e. 4 nm and 75 Hz. The method allows for very sensitive measurements of the contact stiffness as can be seen on figure 1b, even though some measurement noise exists.

Figure 6 displays the variation of stiffness around the general trend  $n_{stiff}$  calculated by a moving average on 18 points. The standard deviation of the stiffness noise is about  $\sigma_n = 0.9 \text{ N.m}^{-1}$ , so the limit detection is chosen such as  $\Delta S > 5 \times \sigma_n$  for all the experiments. Thus, the criterion used is  $\Delta S_{min} = 5 \text{ N.m}^{-1}$  to detect an abnormal contact stiffness evolution (jump).

Figure 6: Evolution of stiffness around the general trend calculated by a moving average on 18 points.

## 3.2 Image analysis

The objective of the image analysis is to distinguish the carbon black aggregates from the fluoroelastomer and silicon matrix. Figure 7a displays the Transmission Electron Microscopy (TEM) observation of the elastomer in gray-scale. An image analysis post-treatment, described in more details in the appendix, is applied to the latter to obtain figure 7b which represents the binary matrix. Black zones are aggregates with logical a value of 0 and the white zone is the fluoroelastomer matrix with a logical value of 1. For this image, the side of one pixel is  $e = 20.67$  nm.

## 3.3 Characterization of heterogeneities

### 3.3.1 From experimental data

The characterization of the jumps is performed based on the hypothesis of a constant material's modulus – i.e. fluoroelastomer matrix and silicon nanoparticles. This equivalent modulus is measured directly via CSM nanoindentation at depth greater than 1800 nm, in order to neglect the heterogeneities. Therefore the modulus used in the following develop-

Figure 7: Isolation of the carbon black aggregates from the elastomer matrix by image analysis. (a) original TEM observation and (b) image analysis result, with the black particles corresponding to carbon black aggregates and the white part corresponding to the elastomer matrix.

ment is not directly the one of the fluoroelastomer and silicon matrix since the addition of carbon black aggregates must somehow increase the stiffness of the whole material.<sup>2</sup> Nevertheless, the use of this equivalent modulus remains a good approximation of the matrix behavior and allows the proposed method to be self sustaining. The reduced contact modulus measured is  $E'_c = 39.5 \pm 5.4$  MPa. This value is significantly higher than the modulus  $E'$  measured by DMA –  $E' = 15$  MPa – since the solicitation frequencies are 75 Hz for CSM and 1 Hz for DMA.

The contact stiffness signal is transformed into virtual contact depth  $h_{stiff}$  via the following equation:

$$h_{stiff} = \frac{\tan(\beta)S}{2E'_c} \quad (10)$$

If the material is homogeneous the expression of  $h_{stiff}$  versus  $h_c$  leads to an affine function with a slope of 1. However, in the case of a heterogeneous material, this curve will present varying slopes depending on the variation of stiffness with penetration depth.

Hence, every slope greater than 1 should represent a case where the contact stiffness is

1  
2  
3 higher than it should be – i.e. an aggregate enters in contact with the tip – or lower than  
4  
5 1 – i.e. the contact between the aggregate and the tip is well established so the increase  
6  
7 of contact area due to the penetration depth increase is less than it should be. The first  
8  
9 criterion applied to detect a jump is the condition  $\frac{dh_{stiff}}{dh_c} > 1.05$ .

11 Another important criterion is the minimum stiffness detection  $\Delta S_{min}$ , introduced in  
12  
13 section 3.1, which states on representativeness of the detected jump compared to the mea-  
14  
15 surement noise. All the numerical treatments leading to a correct detection of the jumps are  
16  
17 given in the appendix.

19 Figure 8.a displays an example of a contact stiffness versus contact depth curve with its  
20  
21 corresponding jumps highlighted by pairs of colored dots.

### 24 3.3.2 From model data

26  
27 For the tip-particle numerical model, the stiffness of the contact  $S$  is estimated by equation 1  
28  
29 with  $E_c^*$  equal to 39.5 MPa and  $A_c$  the projected contact area as determined by image  
30  
31 analysis. By knowing  $S$ , the virtual contact depth  $h_{stiff}$  is calculated with equation 10 and  
32  
33 a similar analysis as for experimental data is performed. In this case, however, the criterion  
34  
35  $\frac{dh_{stiff}}{dh_c} > 1.20$  is used because of numerical noise coming from pixel transformation during  
36  
37 the simulation. All the numerical treatments leading to a correct detection of the jumps are  
38  
39 given in the appendix.

41 The corresponding detection is illustrated in figure 8.b.

## 45 3.4 Estimation of particles area from numerical simulation

47  
48 Figure 9 displays the ratio of indenter perimeter in contact with particles  $p_{part}$  over the total  
49  
50 perimeter  $p_{tot}$ , as a function of the virtual contact depth. This ratio is related to the portion  
51  
52 of one jump attributable to a new particle such as  $\xi = (p_{tot} - p_{part})/p_{tot}$ .

54 These values are calculated for 9 virtual indents. The error bars represents the mean  
55  
56 values and the standard deviations calculated on a range of 100 nm for all the curves. The  
57  
58

Figure 8: Evolution of contact stiffness with penetration depth from (a) experimental and (b) numerical simulation based on TEM observations. Jumps detection is highlighted by pair of dots.

ratio varies from zero to 0.6 as a function of indent's location and penetration depth. Thus it makes the attribution of a constant  $\xi$  value difficult. However, this ratio rarely exceeds 0.4 and lies principally around 0.2. This means that, between this material and a Berkovich tip, the average portion of tip perimeter in contact with particles is 20 %. So, the most probable value of  $\xi$  is 80 %.

In the following results, a value of  $\xi = 0.8$  is used to approach the particles' projected area distribution.

It must be noted that this approach can be used for any kinds of particles shapes. Yet, values and evolution of  $\xi$  are highly sensitive to the particles' shapes and distributions. Therefore, this parameter is material dependent.

### 3.5 Distribution of particles area from numerical simulation

Figures 10 displays the distributions of particle surface density by range of  $0.15 \mu\text{m}^2$ , in a  $40 \times 30 \mu\text{m}^2$  slab of material. This distribution is calculated from the number of particles of a given projected area  $N_{expe}$  and from the total probed area:

Figure 9: Ratio of indenter perimeter corresponding to particles over the total perimeter, as a function of contact depth, for 9 virtual indents.

$$D(A_{part}) = \frac{N_{exp}(A_{part})}{A_{probe}} \quad (11)$$

Where  $A_{probe}$  is the sum of the indentation projected areas at the end of loading, in the tip-particle model framework. This value depends on the number of numerical increments which is fixed during the simulation.

Table 1 provides the probing parameters used to characterize the particle surface density distributions.  $h_c$  is calculated at the end of the numerical loading with equation 13 defined in the appendix. This value depends also on the number of numerical increments.  $S_{max}$  is the average value – with standard deviation – of the maximum stiffness attained during each numerical simulation. Figures 10.a, .b and .c represent the calculated distributions for 9, 16 and 25 indents, respectively, with  $\xi = 0.8$ .

For all the cases, the tip-particle model tends to greatly underestimate occurrences of small particles, as expected from the expression 8. By varying both maximum stiffness  $S_{max}$  and minimum stiffness detection  $\Delta S_{min}$ , a clear evolution of the minimum detectable particle size  $\Delta A_{c, lim}$  is highlighted. Indeed, by decreasing the maximum stiffness  $S_{max}$

Table 1: Probing parameters for characterization of particle surface density distribution

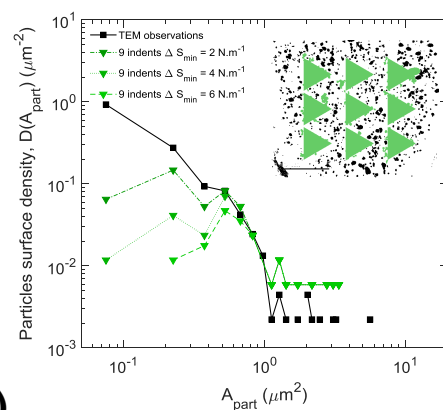

Distrib. Charac.	$S_{max}$ (N.m <sup>-1</sup> )	$h_c$ (nm)	$A_{probe}$ ( $\mu\text{m}^2$ )
TEM	/	/	450
9 indents	$204 \pm 6$	876	170
16 indents	$159 \pm 7$	686	185
25 indents	$101 \pm 10$	410	103

while keeping the minimum stiffness detection  $\Delta S_{min}$  constant, the characterization of small particles distribution is enhanced. Furthermore, the same conclusion can be drawn if  $\Delta S_{min}$  is decreased while keeping  $S_{max}$  constant. In other terms, the best way to detect the broadest range of particle sizes is to perform the smallest indentation feasible.

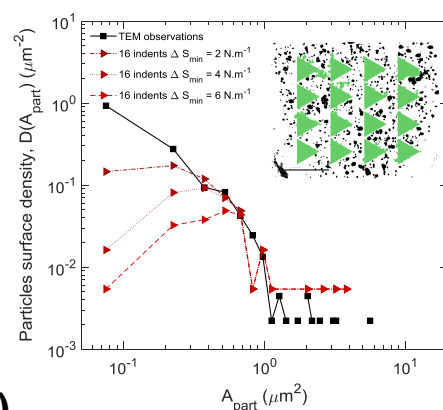

### 3.6 Application to experimental indentation testing

Figure 11 displays the distributions of particles surface density by range of  $0.45 \mu\text{m}^2$ , in a  $40 \times 30 \mu\text{m}^2$  slab of material. The probed areas  $A_{probe}$  are sensibly the same for the TEM observation and the experimental data ( $A_{probe} \approx 450 \mu\text{m}^2$ ). In this case, the minimum particle size fully detected is  $\Delta A_{c, lim} = 1.46 \mu\text{m}^2$ . The best detection threshold for our experimental set-up would allow to attain  $\Delta A_{c, lim} = 0.50 \mu\text{m}^2$  with a maximum stiffness  $S_{max} = 100 \text{ N.m}^{-1}$ . The effect of the stiffness instability's portion attributed to a particle,  $\xi$ , on the distribution calculation is highlighted on figure 11 where the two extremes cases are displayed. As it has been said in previous section, considering  $\xi = 0$  leads to systematic overestimation of the measured particles' area  $A_{part}$ . Hence, the distribution of particle surface density is translated to higher particles' area. The contrary remark is valid for  $\xi = 1$ , which is not obvious in figure 11 since other sources of particles' area  $A_{part}$  overestimation are present. The latter will be explain in the following paragraphs.

Figure 12 highlights the influence of measured matrix's reduced contact modulus on the distributions calculations. It displays the distributions of particles surface density by range

(a)

(b)

(c)

Figure 10: Particles surface density, characterized by image analysis and the tip-particle model with (a) 9 indents, (b) 16 indents and (c) 25 indents. The number of occurrences of a certain particle size is divided by the total probed area – i.e. contact area at maximum depth for indentation data.

Figure 11: Particles surface density, characterized by image analysis for TEM observations and experimentally from the tip-particle model and experimental curves calculated with different level of correction – i.e.  $\xi = 0$  and  $\xi = 1$ .

of  $0.45 \mu\text{m}^2$ , in a  $40 \times 30 \mu\text{m}^2$  slab of material for the same set of experiments.

These distributions are calculated from experimental tests by the tip-particle model with a minimum stiffness detection,  $\Delta S_{min} = 5 \text{ N.m}^{-1}$  and  $\xi = 0.8$ , in yellow and the distribution calculated from TEM observation in black. The three experimental distributions are calculated with the same set of indentation tests with different reduced contact moduli  $E_c'^*$ . The plain circle symbols correspond to the mean value of  $E_c'^*$  and the up-pointing and down-pointing triangles correspond to the standard deviations of the reduced contact modulus, respectively. The choice of the modulus affects the calculation of the distribution such as, for higher modulus the calculated areas of the particles are smaller, see figure 12. This leads to an overestimation of the small particles' surface density and an underestimation of the large particles' surface density. In the other hand, if a lower modulus is taken to represent the matrix, the calculated areas of the particles would be higher.

As for numerical simulation results, the surface density of small particles – i.e.  $A_{part} \leq 0.375 \mu\text{m}^2$  – is greatly underestimated whatever the reduced contact modulus taken into

Figure 12: Particles surface density, characterized by image analysis for TEM observations and experimentally from the tip-particle model and experimental curves calculated with different reduced contact moduli – mean value and standard deviation values.

account. This is due to the model limitations, as explained previously.

Also, the distribution of larger particles is well above the one measured via TEM observations. Here again a parallel can be drawn with the numerical simulations results which indicates that the overestimation of large particles – i.e.  $\Delta A_c > 0.525 \mu\text{m}^2$  – is enhanced by the increase of the indent size. This behavior is related to the indent perimeter and highlights the fact that multiple "small" particles can enter in contact nearly simultaneously with the tip and act as a "large" particle on the measured stiffness. Therefore, the longer the indent perimeter, the higher the probability to detect several particles in the same stiffness instability.

However, this explanation is not sufficient to describe the difference between the experimental particles surface density distribution and the TEM observations. In the case of the TEM observations, the material is assumed to be in two dimensions – the thickness of the sample being around 100 nm – contrary to the experimental set-up where the sample is considered with 3 dimensions. Thus, increasing the indentation size enhances the contributions

1  
2  
3 of deep particles to the measured contact stiffness. The term "surface density" as to be  
4 employed with care when the indentation depth is significantly greater than the particles  
5 size.  
6  
7  
8  
9

### 10 11 **3.7 Correction of the measured distributions** 12

13 The tip-particle model reliability has been investigate through numerical and experimental  
14 analyses and give access to a correct particle distribution within the model hypotheses. In  
15 this paragraph, the proposed correction (equation 9) derived from the tip-particle model is  
16 applied to the numerical and experimental particle distributions.  
17  
18  
19  
20

21 Figure 13 displays the corrected numerical distributions calculated from the same data  
22 set as figure 10, with average values of  $S_{max}$  from Table 1 and different values of  $\Delta S_{min}$  as  
23 shown in Figure 13. An excellent agreement between the TEM observation and the corrected  
24 distributions is shown, whatever the tested conditions – i.e. various  $\Delta S_{min}$  and  $S_{max}$ . Even  
25 if the tested conditions have an effect on the result and must be chosen with care, it is very  
26 pleasant to see that a unique solution can be extracted from the stiffness measurement.  
27  
28  
29  
30  
31  
32

33 Figure 14 displays the corrected distributions of particle surface density  $D(A_{part})$  cal-  
34 culated in the same conditions as in figure 12. These distributions are calculated from  
35 experimental tests by the tip-particle model with a minimum stiffness detection,  $\Delta S_{min} =$   
36  $5 \text{ N.m}^{-1}$ , an average maximum stiffness,  $S_{max} = 310 \pm 49 \text{ N.m}^{-1}$ , a reduced contact modulus  
37  $E'_c = 39.5 \text{ GPa}$  and  $\xi = 0.8$ . The as-measured distribution is represented with circle sym-  
38 bols, the corrected one is represented with diamond symbols and the one calculated from  
39 TEM observation with square symbols. Here again, the agreement between the TEM distri-  
40 bution and the corrected experimental one is reasonable, taking into account the relatively  
41 unfavorable tested conditions.

### 3.8 Tip-particle model limitations

The tip-particle model has been investigated numerically in order to better understand its limitations. We have seen in section 3.7 that the main source of error arises from the loading limitation. This is promising since the measurement bias is expressed by equation 8 which is only a function of experimental inputs  $\Delta S_{min}$  and  $S_{max}$ .

However, some deviations are not due to loading considerations and should come from these model limitations :

- The model tends to overestimate the size of the detected particles since the indenter can enter in contact with several particles at the same time. This configuration is highlighted on figure 15.a where the particles 2 and 3 enter in contact successively with the virtual indent. Figure 15.b displays the corresponding evolution of stiffness with contact depth and one can see that the two particles are detected as one jump. This issue is getting more and more probable as the contact perimeter between the tip and the material increases. Thus, the smaller the indent the less probable the detection

Figure 15: Numerical simulation of indentation applied on the binary image extracted from TEM observation: (a) increments  $t = 19$  and  $t = 20$  the virtual indenter enters in contact with two particles successively ; (b) contact stiffness evolution with contact depth and detection of the stiffness jump.

of several particles at once.

- Only particles in the near surface participate to the tip-particle extension. Indeed, the particles need to be in direct contact in order to play the role of tip's hard extensions. However, with increasing penetration, the elastomer matrix between the particles is more and more confined. Therefore, the participation of deeper particles to the total projected area is enhanced. This also leads to an overestimation of the particles sizes.
- Furthermore, if particles are too close to each other, the tip-particle extension will not allow to isolate the contribution of particles independently.
- Particles are sometimes hidden by a bigger one contacting the tip previously. Hence, the contact stiffness is much higher than in the homogeneous case and the addition of a small area may not be sufficient to generate a stiffness jump greater than the minimum detection limit  $\Delta S_{min}$ . In such case, the particle is not detected and the particle surface density for the concerned range of particle area is underestimated.

## 4 Conclusions

In the framework of highly heterogeneous materials, a new method to characterize the local distribution of particles surface density is proposed. The latter applies to materials presenting high mechanical properties contrast between its different phases. In this study, particles are stiffer and harder by a factor of 100 compared to the fluoroelastomer matrix. Further investigations may address the lower limit of these mechanical properties contrasts.

An extensive study of the tip-particle extension is provided based on numerical and experimental approaches. Therefore, the main conclusions are:

- Quantitative distribution of particles surface density can be measured from stiffness jumps during nanoindentation loading.
- Accuracy of the measured particles' surface density distributions depends on the minimum detectable stiffness jump and the maximum load applied.
- The higher the number of indentation, the more accurate the measured distribution.
- An analytical correction based on experimental parameters can be applied to account for the smallest particles that might have been miscounted.

Nanoindentation testing appears eventually as an interesting alternative to Transmission Electron Microscopy to measure hard nanoparticles local distribution in an elastomer matrix.

# Appendix

## Image analysis

The following treatment steps are applied to the image:

- The gray-scale image is transformed into a logical matrix by mean of an adaptive threshold algorithm available on Matlab<sup>®</sup>. The threshold value is modified as a function of the neighbors pixel mean intensity. The matrix obtained is named  $B_1$ .
- A morphological operation is then applied to isolate the particles' representative elements by specifying a minimum aggregate radius. The matrix  $B$  is obtained from  $B_1$ .
- As it can be seen on the figure 1, some particles are white. Those elements correspond to aggregates that have been removed from the TEM "blade" during their preparation. As a consequence, another adaptive threshold algorithm is applied to isolate them from the matrix and obtain a matrix named  $C$ .
- The matrix containing all the aggregates is then written as  $D = B + \bar{C}$ . Then, the irrelevant pixel groups are removed such as only particles greater than 45 pixels remain. This matrix is represented on the figure 7.b.

## Jump detection

### From experimental data

The post-treatment steps aim at isolating the segments characterized as stiffness jumps:

1. First, an equivalent contact depth  $h_{stiff}$  is calculated, with the hypothesis of a constant and homogeneous reduced contact modulus  $E'_c$ , from equation 10. It is done to normalize the stiffness signal according to the contact depth and allows for a simple criterion to be set:  $\frac{dh_{stiff}}{dh_c} > 1.05$  is equivalent to a jump.

- 1  
2  
3 2. In a second step, a sampling at a constant frequency of displacement is performed.  
4  
5 Originally, the acquisition frequency is fixed at 5 Hz, but since the loading procedure  
6  
7 is exponential according to time, the interval between two consecutive penetration  
8  
9 depths increases with time. The sampling is performed in order to get a 0.8 nm  
10  
11 spacing between the data which is in the same order of magnitude as the intervals  
12  
13 during all the loading procedure – i.e. 0.4 to 3 nm.  
14  
15
- 16 3. Following this step, a numerical derivative is performed by fitting an affine function on  
17  
18 18 points around the concerned contact displacement value. Hence, a moving derivative  
19  
20 is obtained. An example of the resulting treatment is presented on figure 16.a.  
21  
22
- 23 4. This numerical derivative is then compared to the limit detection which is fixed at  
24  
25  $\frac{dh_{stiff}}{dh_c} > 1.05$ , as illustrated by the dashed red line on figure 16.a.  
26  
27
- 28 5. An evaluation of the fit goodness is performed with the criterion  $R^2$  for each calculated  
29  
30 derivative. A segment is considered as a **potential jump** when the criterion 4 is  
31  
32 fulfilled together with  $R^2 > 0.8$  and segment length superior to 1 point, as shown in  
33  
34 figure 16.b with the dashed red line.  
35
- 36 6. Then, each segments satisfying criterion 5 is tested with the conditions  $R^2 > 0.9$ , as  
37  
38 shown in figure 16.b with the dashed blue line. If, at least, one fit satisfies this condition  
39  
40 in the concerned segment, it is still considered as a **potential jump** segment. The red  
41  
42 arrows in figure 16.b represent two cases where  $R^2 < 0.9$  in the segments, which means  
43  
44 that the slope calculated here is not relevant. Indeed, in figure 16.c it is difficult to  
45  
46 assess the presence of a jump in the two concerned areas.  
47  
48
- 49 7. Finally, each segment stiffness amplitude is calculated and only  $\Delta S > \Delta S_{min}$  are  
50  
51 considered as real particles.  $\Delta S_{min}$  is 5 N.m<sup>-1</sup> in our study.  
52  
53  
54  
55  
56  
57  
58  
59  
60

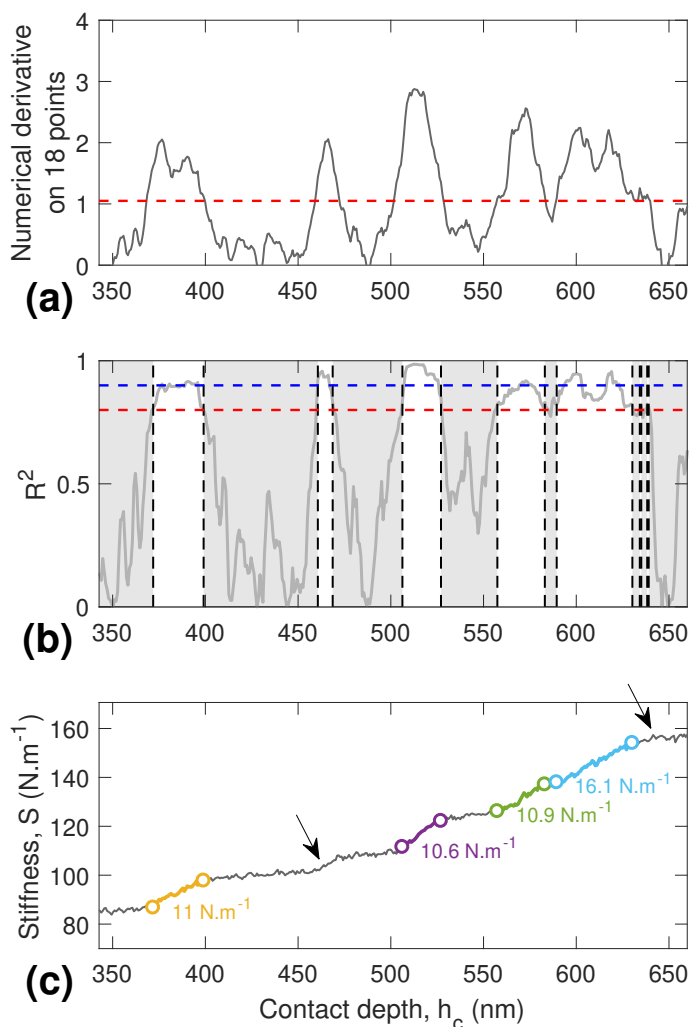

Figure 16: Detection of "jump" segments: (a) Moving derivative of the curve  $h_{stiff}$  vs.  $h_c$  on 20 points, the red dashed line describes the condition necessary to consider a jump  $dh_{stiff}/dh_c > 1.05$  (C1); (b) coefficients of goodness  $R^2$  for the fitted derivative (a), gray bands highlight the segments that do not fulfill the condition  $R^2 > 0.8$  (C2), described by the dashed red line, during enough data points. The blue dashed line describes the other condition to be fulfilled  $R^2 > 0.9$  (C3), the two red arrows point out the state  $C1 = 1$  &  $C2 = 1$  &  $C3 = 0$ ; (c) if all the conditions of figure (a) and (b) are completed, the jump segment is defined by the colored dots pairs.

## From model data

The numerical model is based on the comparison of the image analysis performed on the TEM observation and several virtual indents. Figure 17 represents a numerical indent at

two different simulation increments. On figure 17.a, the virtual indent lies completely in the fluoroelastomer matrix and on figure 17.b the virtual indent touches a particle. The area of contact is displayed in light green.

Figure 17: Numerical simulation of indentation applied on the binary image extracted for TEM observation: (a) increment  $t = 8$ , the virtual indenter lies on the fluoroelastomer matrix ; (b) increment  $t = 14$  the virtual indenter is in contact with particle 1.

Hence, at each simulation step, the pixels corresponding to the three sides of the equilateral triangle are calculated and written as vectors noted ( $\vec{L}_i(t) = [X_i(t), Y_i(t)]$ ). From the three vectors, the triangle is computed and the corresponding pixels in the area are set at logical value of 1, all the other pixels of the matrix are set to 0. This indenter matrix is named  $E_t$  with  $t$  the increment. Then, the matrix  $E_t$  containing the triangle is superposed on the image analysis matrix  $D$  such as  $F_t = \bar{D}.E_t$ . From this resulting matrix, the area of the zone with logical value 1 and containing the initial barycenter of the triangle is registered. The area evolution is calculated by the number of pixels multiplied by the equivalent surface of a pixel such as  $A_c(t) = N_{pix}(t)e^2$  and then stiffness and contact depth can be calculated with following equations:

$$S(t) = 2E_c'^* \sqrt{\frac{A_c(t)}{\pi}} \quad (12)$$

$$h_c(t) = e(\|\vec{L}_i(1)\| + 2(t - 1) \tan(60)) \frac{\sqrt{3}}{6 \tan(65.27)} \quad (13)$$

With  $\|\vec{L}_i(1)\|$  the length of one side of the equilateral triangle at increment 1. The angles are relative to the Berkovich geometry.

Finally, to evaluate the presence of stiffness jump the ratio between the virtual contact depth  $h_{stiff}$  (equation 10) and the contact depth  $h_c$  is calculated. The criterion  $\frac{dh_{stiff}}{dh_c} > 1.20$  is applied to detect the stiffness instabilities. If this relation is false, the ratio is set to zero. The segments corresponding to jumps are then isolated and their stiffness amplitude  $\Delta S$  are compared to the minimum stiffness detection  $\Delta S_{min}$ . As for experimental treatment, only  $\Delta S > \Delta S_{min}$  are kept.
